In acquiring information with a view to laying down on paper the position and extent of mine workings, the magnetic needle has long been employed. In using the needle, however, it is necessary to know the declination in relation both to the locality and to the time, for it varies not only in different places but also from year to year. At the present time in London the needle points 17° to the west of the true north, an amount that annually decreases at the rate of about seven minutes. In the year 1580 the needle in London pointed 11° 36′ to the east of the true north; in 1663 it pointed due north, and it attained its greatest western declination of 25° 41′ in 1818. Since that date it has regularly decreased. The first observation of the declination appears to have been made in Paris in the year 1541. Regular observations, however, were not made until the middle of the 17th century. In a scarce work in my possession, bearing on the title-page:—"*Humane Industry*, or a History of most Manual Arts, Deducing the Original, Progress, and Improvement of them. Furnished with variety of Instances and Examples, showing forth the excellency of Humane Wit. London, Printed for *Henry Herringman*, and are to be sold at his Shop at the Blew-Anchor in the Lower Walk of the New-Exchange, 1661," the importance of a knowledge of the declination is fully appreciated, for it is stated that the compass "is not brought yet to that perfection, but that it requires some rectification and amendment; for the Magnetique Needle doth not exactly point to the North in all Meridians, but varies and swerves (in some places more, in some places less) from the Direct posture, Configuration, and Aspect of the North and South, which puts seamen to much distraction, and makes them run oftentimes on dangerous errors. *Van Helmont*, a great *Paracelsian* of *Germany*, professeth a readie way to rectifie this grand inconvenience, namely how to make a needle that should never vary or alter from the right point, which may be performed by a strong imagination, as he saith, thus; If a man in framing the Needle shall stand with his back to the North, and place one point of the Needle (which he intends for the North) directly towards himself, the needle so made shall always point regularly and infallibly toward the North without variation. I wish that some *Fancy-full* man of an exalted imagination would make some Needles for experiments after Helmont's direction, since it is a business of great concernment to the publique Weal, to have this business rectified."

A description of the miner's compass is given in the oldest treatise on mining, a work written in German, and published in 1505. No copy of the first edition of this "well arranged and useful little book," as the anonymous author modestly calls it, is known to exist, and copies of later editions are rare. The title-page of the 1539 edition bears the following words:—"Ein wolgeordent un nutzlich büchlin wie man Bergwerck suchen und finden sol | von allerley Metall | mit seinen figuren | nach gelegennheyt, dess gebijrges | artlych angezeygt | Mit anhangenden Bercknamen | den anfahenden Bergleuten vast dienstlich, mdxxxix." The book is written in the form of a dialogue between Daniel, the mining expert, and Knappius the young. The woodcut of the miner's compass shows that the dial is divided, not into degrees, but into twice twelve parts or hours, the north being marked as midnight, the south as noon, the east as morning, and the west as evening. The accompanying description appears to refer to the declination of the needle; but the passage is so obscure, that Dr. H. von Dechen, who has made a careful study of this work, regards its meaning as doubtful. In the library of the Freiberg School of Mines, there are copies of four editions of this interesting work. The libraries of Dresden and Munich possess the 1518 and 1529 editions, and the Germanic Museum at Nuremberg has also a copy of the 1518 edition. The copies available in this country are later reprints. In the library of the Museum of Practical Geology, this work will be found in two volumes—"Ursprung und Ordnungen der Bergwerge im Königreich

Böheim, Leiptzigk, 1616," and "Corpus juris et systema rerum metallicarum, Franckfurt, 1698."

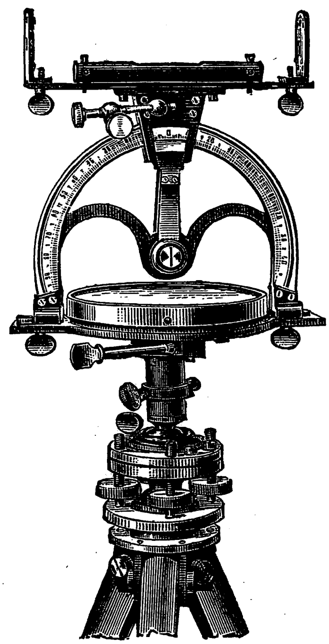
The compass described by Agricola, in the fifth book of his *De re metallica* (1556) is of a very primitive character. It consists of a series of seven concentric circles, filled with wax of different colours; in the middle is a depressed receptacle to contain the magnetic needle. The dial is divided into twice 12 hours, a mode of graduation still frequently used in German mining dials. When in use, the instrument was so placed that the needle pointed to the north, and a scratch was then made in one of the wax circles, to indicate the direction, the bearing of which was required. The laying down of the results was effected by repeating the survey at the surface, the object of surveys in those days being merely to determine how near the underground workings were to the boundary of the concession. An old compass of this type, marked 1541, found at Neudorf, in the Hartz, is preserved in the Clausthal collection, and a similar one, that belonged to Galileo, is shown in Florence.

In the 17th century mines were surveyed in a somewhat similar manner, as is shown by the description of the method of surveying adopted in the Derbyshire lead mines, given by Thomas Houghton, writing in 1688, in his "*Rara avis in terris*, or the compleate miner." Even, in the middle of the last century, dialling was carried on with appliances of a very primitive character. "The instruments used," writes Dr. W. Pryce, in 1778, "are a compass without a gnomon or a style, but a centre-pin projecting from the middle of the compass to loop a line to or stick a candle upon, fixed in a box exactly true and level with its surface, about 6, 8, or 9 inches square, nicely glazed with strong white glass, and a cover suitable to it hung square and level with the upper part of the instrument; a 24-inch guage or two-foot rule, and a string or small cord with a plummet at the end of it; a little stool to place the dial horizontally, and pegs and pins of wood, a piece of chalk, and pen, ink, and paper." Dr. Pryce warns "those who take no account of the points or angles of the compass, but in lieu thereof chalk the bearing of the line they measure with on the board the compass lies in; for if they are not exceedingly careful and precise in their operations, they may commit almost unpardonable and irretrievable blunders. Yet formerly, before penmanship and figures were so generally understood and practiced among the common Tinners, as they are at present, most of our Mines and Adits were dialled for in this manner."

Towards the end of the last century, the dial was fitted with sights, by means of which the direction of the station-line could be taken with precision, and successive improvements introduced in the construction of this original miner's dial have finally resulted in the beautifully constructed instruments that you see exhibited to-night.

In its simplest form, the miner's dial consists of a circular box of brass divided into 360°, with a magnetic needle freely suspended on a finely pointed pin fixed in the centre of the circle. The instrument is provided with a glass cover, and also with a brass lid to protect it when not in use. Perpendicular to the horizontal plane of the instrument are two brass plates, or sights, with fine slits cut in them, carrying plain wires. The compass box is attached to a tripod-stand, a ball and socket joint furnishing the means of levelling the instrument.

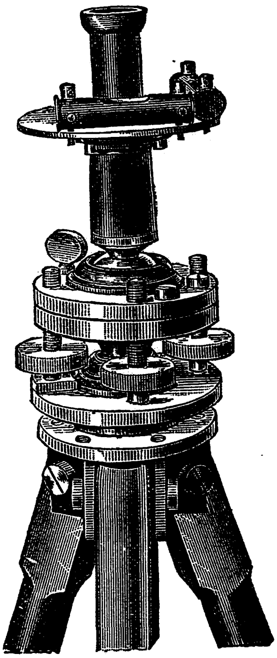
Fig. 2.



In later forms, levelling screws are added, and two small spirit levels are placed on the dial plate. For taking vertical angles, in the old type of miners' dial, the brass cover protecting the glass was used as a clinometer. A vertical arc is now used, which may be placed

at pleasure across the central line of the compass (Fig. 2, p. 811). This is in general use in metalliferous mines. In collieries, where the vertical angles required are never excessive, a side arc is usually employed. In the best form of side arc, invented in 1850, by Mr. John Hedley, H.M. Inspector of Mines, the sights are carried by an outer ring concentric with the dial. In order that the compass graduations shall not be obstructed when the vertical arc over the dial is used, the standards in the Whitelaw dial are dispensed with, and in their place is a movable semi-circular arc, carrying the bar with the sights. In the Thornton dial, the vertical arc is made to fold down out of the way of injury when the instrument is carried from place to place.

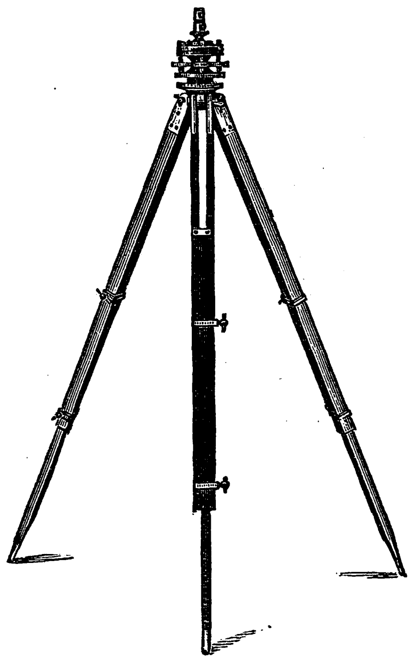
FIG. 3.



On account of the increasing use of iron and steel in mines in the form of rails, props, or machinery, the number of mines in which the magnetic needle is not affected is extremely small. It is therefore necessary to employ an angle-measuring instrument that shall be independent of the needle. An instrument of this kind consists of a horizontal circle graduated in 360°, with a circular plate above it, capable of independent rotation. Since either of these plates can be fixed while the other moves, a means of measuring angles is afforded. All modern miner's dials are made on this system, the method of surveying by measuring angles without the use of the needle being known as "fast-needle dialling." The angles are read with great accuracy by means of verniers, and when a telescope is fitted on the vertical arc in place of the sights, the instrument becomes to all intents and purposes a theodolite that can be used for field-surveying.

In order to ensure accuracy, it is advisable in underground surveys to use three tripods, one for the instrument and the others for the lamp or candle. The latter is fitted in a special holder (Fig. 3) provided with two spirit levels, and capable of being levelled by a ball and socket joint and levelling screws. One of the best forms of tripod is that made by Messrs. E. T. Newton and Son, of Camborne, who employ slotted legs with thumb-screws for tightening them when any wear takes place owing to the shrinkage of the wood under climatic influences. For surveying over very irregular ground, these tripods (Fig. 4) are provided with sliding adjustable slotted oak legs, a device that greatly economises time in levelling the instrument.

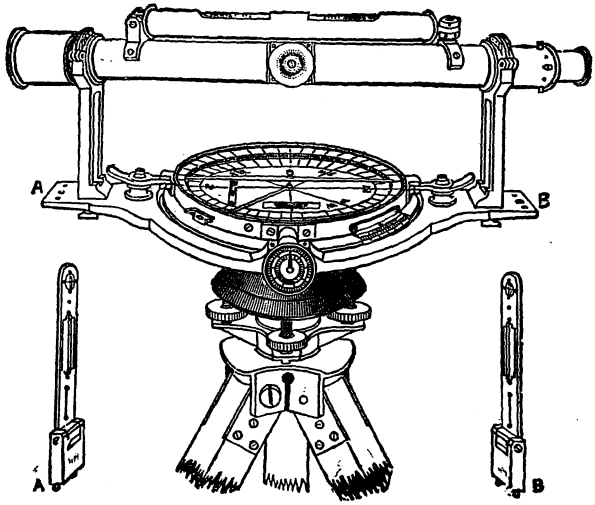
FIG. 4.



One of the latest forms of dial, and one presenting many interesting features, is the Henderson dial. In place of the horse-hair sights so largely used, a split-sight, consisting

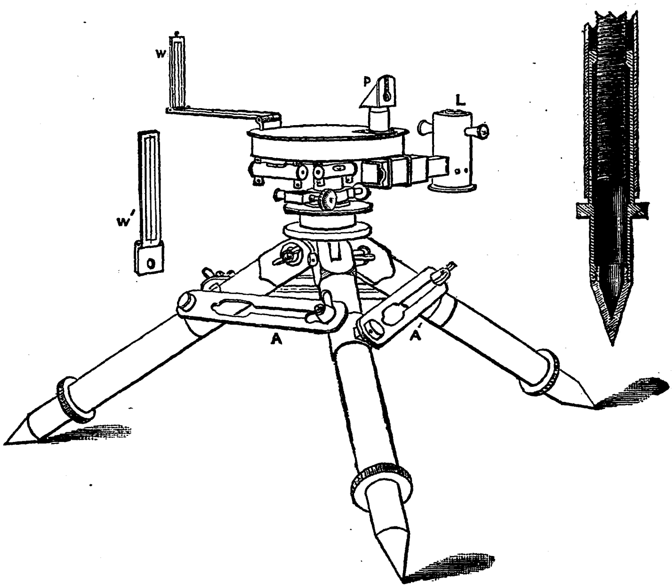
of a fine slit in a metallic plate, is adopted. The needle is mounted on a ruby, in place of the ordinary agate. To the north-seeking end of the needle an aluminium vernier is fixed, so that magnetic bearings can be read with great precision. Lastly, there are two sets of folding sights, one pair revolving within the other. The fixed sights are always

FIG. 5.



in line with the back object in fast-needle dialling, whilst the inner or revolving sights adjusted to the forward object give the angle of deviation from the original direction. This enables any error made in the progress of the survey to be at once detected. The use of two pairs of sights is not altogether new. A similar idea is made use of in the auxiliary

FIG. 6.



telescope (*lunette témoin*) in some French theodolites, and the two pairs of sights are also adopted in a graphometer or primitive theodolite in my possession, made at Brunswick before 1630.

The best instrument for colliery use is the Davis dial (Fig. 5), the special features of which are the Hedley form of side arc for taking vertical angles, and an arrangement by which bearings may be taken simultaneously with

the magnetic needle and with the vernier, the latter automatically checking the former. In the latest form of this instrument, the side arc is replaced by a fixed circular box—1¾ inch in diameter—with a hand traversing a dial-plate divided into 90°. This new form of arc presents the advantage of being so compact that it does not interfere with the manipulation of the screws under the body of the dial. For facilitating the levelling of this instrument—an American invention — the Hoffman joint has been adopted, a tripod head that combines the play of the ball and socket joint, with the accuracy and rigidity of the levelling plates of the theodolite.

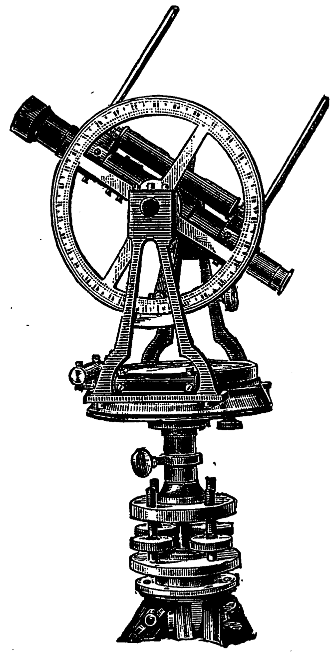
In the time at my disposal it is impossible to specify all the improvements that have been introduced in the construction of the miner's dial. All these improvements tend to make it approach more nearly to the theodolite. An experiment of a novel character, however, has been tried by Mr. Stanley, who has adapted the prismatic compass of the military surveyor for use underground. In this instrument (Fig. 6, p. 813) the floating ring is made of transparent celluloid, and light is thrown under it from a small movable lamp by means of a large prism. The adjustment to level the compass-box is effected by screws placed longitudinally up the legs.

We now come to the instruments for measuring angles, whether horizontal or vertical, with great precision. Of this class the theodolite is typical. There are many forms of theodolite, but the principle in all is the same. A telescope is mounted on both a vertical and a horizontal axis, in such a manner that the partial or complete horizontal or vertical rotation of its optic axis may be measured in degrees of arc and their fractions. The three chief types of theodolite are (1) the plain theodolite, in which the vertical arc is a semicircle; (2) the transit theodolite, with a complete circle as vertical limb; and (3) the Everest theodolite, in which the vertical limb consists of two opposite sectors, of about 90° each. It is unnecessary for me to discuss the construction of these instruments, as this subject was exhaustively dealt with by Mr. W. Mattieu Williams in a course of Cantor lectures, in 1879, and more recently in Mr. W. F. Stanley's admirable treatise on surveying instruments (London, 1890).

Since 1832, the theodolite has been used more or less in all mine surveys, where great accuracy was desired. Theodolites specially constructed for underground work are now made in great numbers by the Continental and American instrument makers. In this country, however, though the theodolite is used to a certain extent in mine surveys, the tendency has been to improve the construction of the miner's dial, making it more and more like the theodolite, so that with it results can be obtained as accurate as those made with a Continental or American mining theodolite of the same size.

The mining transit theodolite (Fig. 7) made by Messrs. E. T. Newton and Son, of Camborne, is furnished with a large (6 inch) compass box, so as to give greater accuracy in the readings of the needle than is possible with the small compass box usually fixed to English theodolites.

FIG. 7.



Besides the telescope, there is a pair of ordinary sights for work in confined spaces underground. When the theodolite is used underground, it is necessary to illuminate the cross-wires of the eye-piece; and in this theodolite, this is effected by means of a hole drilled in the supports, and a small mirror placed at an angle of 45° in the axis of the telescope, a lamp being fixed near the supports. In other cases, the illumination is effected by reflecting the light into the telescope through the object-glass.

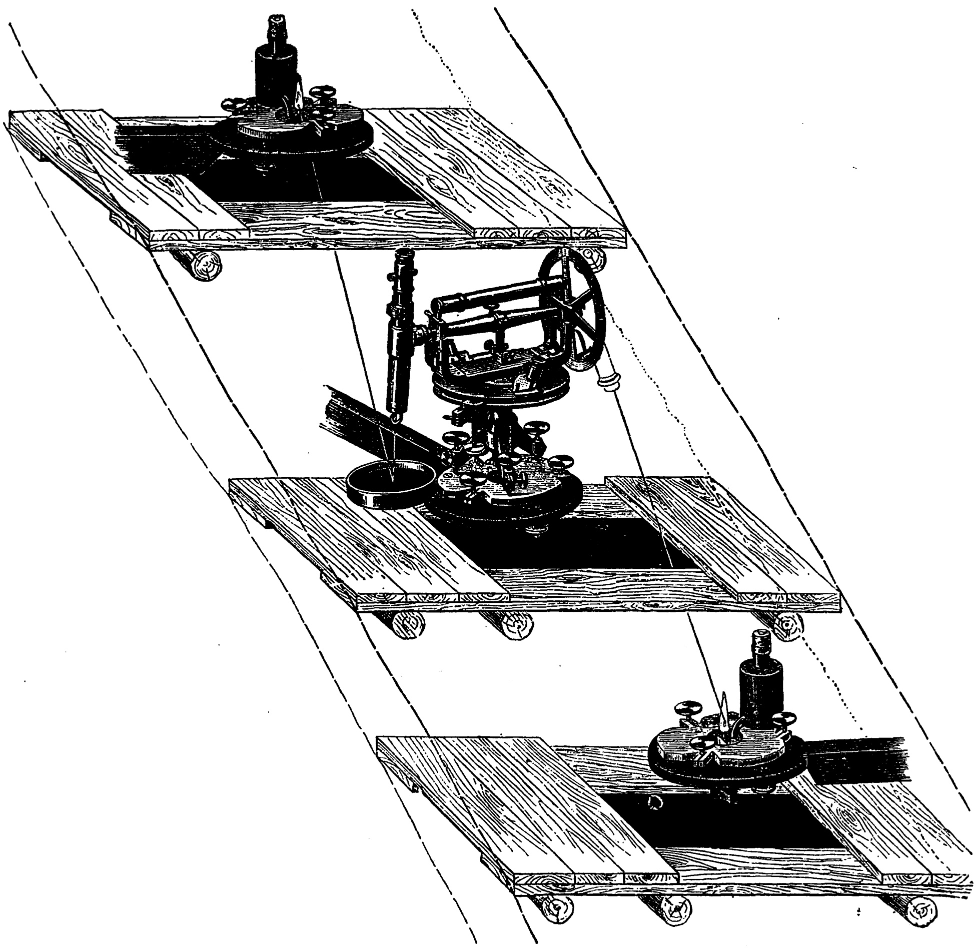
The German transit theodolites specially constructed for underground work differ in many respects from the English ones. The

instrument is invariably supported on three levelling screws, instead of on the four that are usually employed in this country. It rests on a tripod table with extensible legs, and risk of upsetting is prevented by a screw fixed in the tripod-head acting against a spring which draws the instrument constantly down when attached. The horizontal circle is protected from dust by a metal plate, and white porcelain shades are supplied for deflecting the light on to the verniers.

For surveying in shafts, it is frequently found advisable to use a theodolite with an eccentric telescope, a diagonal eye-piece being used for vertical sighting. In place of this an artificial horizon may be used, it being then merely necessary to sight down to the image of the flame. Fig. 8 shows the mode of using the artificial horizon adopted by Professor Borchers in the German mines.

A useful theodolite (Fig. 9, p. 816) for surveying work is that designed by Mr. Stanley. It has an eccentric telescope, with a pair of sights for use in confined spaces. These are made on a new principle, the sights being placed in two windows, and formed of two needle points of platino-iridium. The height of the instrument is 6 inches, and its weight 13 lbs. Two other theodolites exhibited here to-night present features of novelty. (1) The 6-inch transit theodolite made by Messrs. Davis and Son shows the application of the Hoffman joint and centering-plate to instruments of this class. This theodolite is furnished with a trough compass, in which the needle is contained in a long narrow box, whereby a considerable economy of space is effected. (2) The 5-inch telemetrical theodolite or tacheometer,

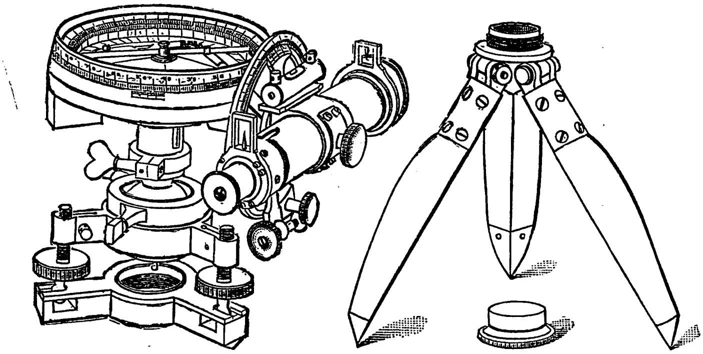
FIG. 8.



made by Mr. W. F. Stanley, shows the manner in which chain-measurement may be dispensed with, the distances being obtained by measuring the image of a distance staff, as it appears at the focus of the telescope, a method of surveying that is described at length in a paper communicated to the Institution of Civil Engineers in 1888 (vol. xci. p. 282). In this instrument the work is not so much built up in pieces, as is usual in other theodolites, but every casting is, as far as possible, shaped out of the solid to the finished form, so that great lightness and rigidity is obtained.

The adaptation of aluminium to the construction of surveying instruments, where lightness is important, is well illustrated in some of the instruments exhibited. On inspecting these instruments, you will see that the castings are free from blow-holes, and that they dress up cleanly. An advantage that aluminium presents over brass is its resistance to corrosion by the atmosphere and moisture. It does not require a coating of lacquer, as brass instruments do, and its unprotected surface keeps clean and bright. The great advantage of lightness will be readily appreciated by those who have had to carry surveying instruments of the usual construction through the tortuous passages of mines, and up the sides of steep mountains, where the slightest weight becomes a grievous burden. Messrs. J. Davis and Son, who are using aluminium for the construction of mine-surveying instruments, inform me, however, that they find it a very awkward metal to work. It is almost impossible to cut a good thread, and, in the more important parts of the instrument, they find it necessary to bush with gun-metal. From their experience, they think aluminium is not suitable for parts of instruments where an occasional stress has to be borne, as, when once strained, it is almost impossible to restore the original shape and adjustment.

FIG. 9.



In underground surveys, for long station-lines, a candle-flame is the best object to sight, care being taken to shield it from draughts. With shorter lines it is advisable to sight a plumb-line suspended from the angular point. In the anthracite mines of Pennsylvania extremely accurate results are obtained with a plummet-lamp, a brass lamp suspended by two chains from the angular point and terminated below in a conical plummet. When the safety lamp has to be used, it may be supported on a truly horizontal tripod-rest, and in this case it is advisable to use three tripods, a central one carrying the instrument, and two others carrying safety lamps in brass cups for back- and fore-objects respectively.

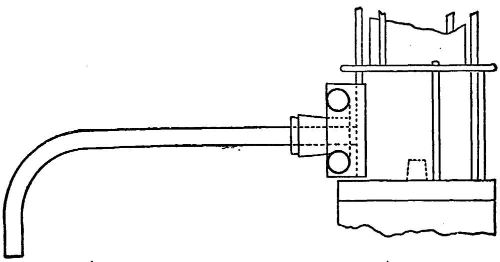
In reading the graduations of the theodolite, a brass lamp, free from iron, should be used. Unfortunately, all safety lamps give a poorer light than the open lamp or candle, and their construction will not permit of the flame being brought near the verniers. The supply of light necessary for reading the verniers of theodolite underground is, therefore, a source of considerable difficulty to the mine surveyor. For this purpose, I have seen the electric light successfully applied in the Schemnitz mines in Hungary, where incandescent lamps are used as objects to be sighted; and a smaller incandescent lamp is used for reading the verniers, the electric current being supplied from an accumulator.

In fiery collieries, where the dim light of a safety lamp has to be used, the inconvenience is especially great. Attempts have been made to increase the illuminating power of such lamps by the addition of lenses or reflectors, with more or less satisfactory results.

An ingenious device recently suggested by Professor Brathuhn, of the Clausthal School of Mines, will probably come into general use. To two of the rods outside the glass cylinder of the safety lamp (Fig. 10) a small plate is fastened by two screws. In the centre of this plate, opposite the flame, a tube is inserted, and into this a bored cork fits. Through the bored cork passes a curved glass rod, with a circular section 0·43 inches in diameter. The light which passes in at the terminal surface is totally reflected by the curved surfaces of the rod, and passes out at the lower end in full intensity. The free end of the glass rod, which can easily be moved in its cork-holder, is placed over the vernier, and a steady adequate light is obtained. Even in mines free from gas it appears worth while to use a light safety lamp for theodolite work, as the flame is so steady and so free from smoke.

The Continental method of surveying mines with the magnetic needle consists in suspending a compass and a clinometer to a

Fig. 10.



stretched cord representing the line of sight. The compass and the clinometer are read, and the length of the line measured. In this way the bearing and inclination of the station line are determined, and the plotting length is calculated. The hanging compass, which was invented by Balthasar Roessler, who died at Altenberg, in Saxony, in 1673, is so constructed that it shall assume a horizontal position when suspended to the cord. The compass may be removed from the hanging-instrument and placed in a plotting-frame, a truly rectangular plate of brass with a raised ring in the middle for the reception of the compass box. The survey is thus plotted with the actual instrument used to make it, and consequently with the same degree of approximation. Care must of course be taken to avoid the presence in the drawing-office of iron objects that may affect the needle. Indeed, at a large French colliery, a drawing-office has been built in which all the ironwork has been replaced by copper, for the purpose of employing this instrument without inconvenience. The hanging compass in Germany and France is being replaced by the theodolite; but it is still found useful in narrow workings. It is occasionally used in America. Thus, in surveying the Longdale iron mine in Virginia, Mr. G. R. Johnson has found it a useful auxiliary. The four main adit levels of the mine having been surveyed, and their entrances connected by level and theodolite lines, it remained to survey the stopes and workings in order to make a complete map, and to test the accuracy of the foregoing work. To do this with the theodolite and level was out of the question, both on account of the roughness of the workings, and also because they were much too small—so small in places that a man could scarcely crawl through them. The hanging compass was consequently used with very satisfactory results, the ends of the survey coinciding with the corresponding points determined in the theodolite survey.

In illustration of this lecture the following instruments were exhibited :—

By the Department of Science and Art.

Small mining transit theodolite, from the South Kensington Museum.

Safety lamp for reading verniers underground, from the School of Mines Collection.

By Messrs. Davis and Son, Derby.

1. Six-inch Davis's improved Hedley dial, with Hoffman patent joint, telescope and sights interchangeable.
2. Five-inch Davis's improved Hedley dial, with small Hoffman joint.
3. Four-inch miner's dial, with ball and socket joint.
4. Hoffman joint in aluminium.
5. Dialling lamp.
6. Davis's dialling lamp.
7. Six inch transit theodolite, trough compass, Hoffman joint, and centering plate.

By Mr. W. F. Stanley, Holborn, W.C.

1. Outside-reading miner's dial.
2. Prismatic dial.
3. Hanging dial.
4. Lamp with fittings for extra tripod.
5. Electric lamp for surveying.
6. Five-inch new model, telemetrical theodolite, telescope supports and axis in one casting, telescopic

tribrach mechanical stage, subtense points for taking distances, trough compass.

7. Mining transit theodolite.

By Mr. Steward, Strand, W.C.

Francis's mine-surveying instrument.

By the Lecturer.

Agricola's mining compass.

Graphometer of 1630.

Miscellaneous.

THE AGRICULTURAL POPULATION OF HUNGARY.

Sir A. Nicolson, H.M. Consul-General at Buda Pesth, says that Hungary may be divided into four main sections. The most important of these sections is the Alföld, lying in the heart of the land, and probably the most fertile plain in the whole of Europe. The second section is the northern portion of Hungary, which extends between the Danube and the Theiss. This is a mountainous, wooded district, where agricultural operations are carried on with difficulty, and rarely with success. The third section is on the western bank of the Danube, forming a district skirted by the Danube, the Drav, and the Austrian frontier. In the midst of this district is the great Bakonya forest, and the Platten or Balalon lake, a fertile region inhabited by the most industrious population of Hungary. Transylvania forms the fourth section, a hilly, wooded country, with a cold, damp climate, principally the region of mines and forests. The majority of the population is composed of Roumans, or Wallachs, the south-eastern portion being inhabited by Hungarian Szeklers and German Saxons. Agriculture is variously pursued in the different regions. The fertile plain of the Alföld is eminently adapted to an extensive system of agriculture, but owing to the scattered and scanty population, the large estates during harvest time are obliged to procure labourers, and frequently for the whole year, from the more thickly populated and less fertile regions in the north of Hungary. The labourers on the Alföld enjoy the most prosperous existence; their wages are the highest, and the position of the hired hand is a satisfactory one. It is in the Alföld that the pure Magyar is to be found in the greatest number. In Upper Hungary, the stony and mountainous character of the region, with its colder and damper climate, is little suited to corn growing, and potatoes are the chief product. The population, who are almost entirely Slovaks, is very dense. Large properties are seldom to be met with; and that portion of the inhabitants who have no land of their own are compelled either to work in the forests or to migrate to the number usually of about 10,000, during the harvest, to the Alföld. Moreover, there is a very considerable emigration annually of Slovaks to the United States. There they work in the mines or at some heavy manual labour, but almost invariably return to their native land after a few years' absence. The Slovak, generally speaking, is in a backward condition, intellectually but little developed, living on a sparse and vegetable diet, and though he is said to possess the simple virtues of the uncivilised, he is still a rude, unlettered individual, given to strong drinks, and with few desires of an elevating character. In the third section, which may be said to form the western division of Hungary, the population is fairly numerous and the most economical in the whole country, the soil fertile, the wages high, and the cultivation careful and productive. The fourth section, Transylvania, has somewhat similar conditions to those existing in Upper Hungary. The cultivation of the land is conducted on very primitive methods, and the condition of the labourer is far less favourable than that of his fellow in the Alföld or in the western division. The population is numerous, chiefly Rouman, who are content with a minimum of the means of existence; and if they can satisfy their daily wants, are with difficulty induced to undertake any further work. The Saxons chiefly inhabit the south-eastern portion of Transylvania, are few in numbers, but industrious and prudent. They prefer town life rather than to work in the fields. The Hungarian Szeklers dwell principally in the extreme east of Transylvania. They are intelligent and enterprising, and are almost without exception engaged in agriculture. They are not, however, entirely satisfied with their lot, as, although they are pure Magyar, probably the descendants of the original settlers of that race, they emigrate in considerable numbers into Roumania, where they frequently change their religion and nationality, and remain in their adopted country. The field labourers may be classified into (1) the hired hands, (2) the tobacco labourers, (3) the zsellers, (4) the day labourers, and (5) the contract labourers. The difference between these several classes is not very great. It is almost the general rule for even well-to-do peasant proprietors to send out their children as day labourers, while the smaller peasant proprietors assist in all the processes of the maize cutting and harvesting in return for a share of the produce. The tobacco labourers are in a peculiar position. Tobacco is a State monopoly in Hungary. The tobacco labourers form regular colonies on the properties of the large tobacco cultivators. They make contracts with the proprietors, of which the following are the usual conditions. The proprietor gives the tobacco labourer, who has usually a family to support, from $1\frac{1}{4}$ to $2\frac{1}{2}$ acres of land, a dwelling-house and the necessary forage for one or two horses, and also 50 per cent. of the price of the tobacco which he has grown. The labourer has to undertake all the operations and work connected with the

tobacco cultivation, and to see to its transport to the place whence it is forwarded. The material condition of these labourers are said to be very prosperous. The zsellers are reminiscences of the old system of serfdom abolished in 1848. They receive cottages and a small plot of ground, and are bound to furnish the proprietor in return with so many days work in the year. In the Alföld the average day's wage during the harvest and haymaking seasons is 2s. 8d. for male field labourers, while in Transylvania and Upper Hungary the maximum daily wage may reach 1s. 4d. to 1s. 6d. During the harvest it is frequently the custom to pay the wages partly in kind, if not entirely, and in such cases one-eleventh or one-twelth of the harvest is given. With maize one-third to one-fourth is given, if the labourer undertakes the cutting, crushing, and transport. In hay cutting one-half or one-third is distributed, and one half of the second crop. The day labourers are usually provided with cottages. The contract labourers are engaged either for a whole year, as is generally the case when they come from a distant district, or for certain seasons. The contracts are written ones, drawn up before an authority, and concluded with the chiefs of the several groups of labourers. Their wages vary according to local requirements, but are much the same as those of the hired hands, who receive on an average an annual wage varying from about £2 to £5; 24 metric centners (metric centner is equal to about 200 pounds avoirdupois) of rye, 6 metric centners of wheat, and the same quantity of barley. In addition they are provided with free lodging, wood for firing, and sometimes clothing.

CANARY BREEDING IN GERMANY.

The United States Consular Clerk at Berlin says that third in money value among the articles exported to the United States from the Consular district of Hanover during the last quarter were canaries. For more than a century canary breeding has rendered bare existence a possibility to many poor people in Germany, and has brought a competence to others. Fifty years ago the industry had grown to such dimensions, that it became necessary to seek a foreign outlet for the trade. Salesmen were accordingly sent out, first through the Rhine districts, then to Belgium and Holland, and, soon afterwards, to England. The German canary dealers soon succeeded in establishing a brisk trade with St. Petersburg, the birds being brought by carrier to Lubeck, and thence forwarded by ship to their destination. Encouraged by their success, the German bird dealers, about the year 1850, began making shipments to New York. This proved a very profitable business, and after the introduction of steamship lines, birds were sent to South America and Australia. Canary breeding in Germany has, from the commencement, been chiefly a home industry of poor people. The principal seat of the industry was formerly the Hartz mountains, where the poor mountaineers, engaged chiefly in the timber and mining industries, were in great need. Almost every family then had in their sitting-room, the bedroom, or the garret, a breeding place for their birds. In the summer, the food necessary for the birds was easily obtained, and before the winter came the dealer had purchased them. After the Hartz mountains became more frequented by visitors desirous of benefiting by the pure Hartz air, the poverty of the mountaineers was diminished, and the canary industry fell off more and more. At present only fine singers are bred in the Hartz, and for these the dealer must pay a high price. The industry was then transferred to Eichsfelde, in the province of Hanover, where there are many very poor weavers. Nearly all of these are now engaged in breeding the cheaper varieties of canaries. The industry exists also in the poorer districts of Hesse, in the great Luneburg Moor, in parts of Westphalia, and among the Sudetic mountains (Erzgebirge) in Saxony. In the fruitful districts of the province of Hanover, where there is not so much suffering, the business is not carried on extensively. In recent years large numbers of birds have been bred in the cities, chiefly as a pastime. The extent of the canary breeding industry is shown by the fact that about 250,000 canaries are bred every year in Germany. Among the foreign markets, the first is the United States, which takes, in round numbers, 100,000 birds annually. Next in importance is the English market, which takes about 50,000 per annum. Then comes Brazil, Chile, the Argentine Republic, and Australia. To these countries salesmen are sent with canaries every year. The remaining birds, especially the finer Hartz mountain birds, are sold in Germany, where more value is attached to fineness of song, and where higher prices can be obtained than anywhere else The average price for ordinary canaries is from three to four marks for males. Hence the canary industry adds about 1,000,000 marks per annum to the national wealth of Germany, and this amount goes chiefly into the hands of the poorest class. The growth of the industry is said to be due to two causes—(1) the German bird dealers have already been very enterprising, and (2) the canaries bred in Germany are said to sing better than any others. About two-thirds of the canaries exported annually from Germany to the United States are imported by a German resident of New York, whose German home is at Ahlfeld, in the province of Hanover, whither the birds are brought from all parts of Germany. At Braunlage, in the Harz, this dealer has a factory which is capable of turning out every day the material for a thousand bird-cages. This material is given out to the peasants, who make the cages at home. From Ahlfeld the birds are shipped to New York *viâ* Bremen, accompanied by attendants. Each attendant has under his care about a thousand birds, each in its own wooden cage.

PRODUCTION OF INDIA-RUBBER IN BORNEO.

There is a royalty charged on rubber collected from the jungles of Borneo of 10 per cent. *ad valorem.* The different species of the plant found are, according to the United States Consul at Singapore, (1) *Manungan pulan,* which comes chiefly from North-West Borneo; it is a *Willughbeia barbidgei,* and is specially identical with the "gutta-singgarip" of the peninsula; (2) *Maugan buyok,* said to yield the best gutta of the Borneo forest; it is a *Leuconotis engenifolius*; this specie is also found in small quantities on the peninsula; (3) *Manugan manga,* which yields a very good gutta, is possibly a *Willughbeia,* as also is *Surapit,* for the latter yields the same milky exudation as *Manungan pulan,* but is said to be a bad gutta, and seldom collected. *Bertabu,* or *Petabo pulan,* is referred to as of little value as gutta, except perhaps for adulterating the better kinds. The other kinds of gutta met with in the Malay Peninsula are—(1) *Singgarip putch,* or *Gutta sudek*; (2) *Singgarip hitam*; and (3) *Gutta jelutong*—the latter is only used for adulterating. The gutta-percha production and export is much larger than the trade in india-rubber properly so called. The name is given to the inspissated juice, which is produced chiefly by *Dichopsis gutta,* called by the natives *getah taban merah,* and often confused with caoutchouc. The tree is of large size, from four to five feet in diameter, and from 100 to 200 feet in height. When growing in the forest it has a clean, straight stem, and it may be generally distinguished by the rich brown colour of the under surface of the leaves. The flowers are small, white, and divided into six petals and six sepals. The seeds—generally two in each fruit—are oily, and are eaten by birds and monkeys. It flowers in March, and the fruit ripens in June. The method of collecting the gutta is as follows:—A tree having been selected is felled, and as it lies on the ground, rings about an inch broad are cut in the bark at intervals all along the whole length of the trunk and of the branches with a parang, or Malay knife. These cuts soon become filled with the white, cream-like sap, and in about half an hour the gutta will have separated from the aqueous portion of the sap, and may be removed by rolling a small ball of it round in the cuts, to the edge of which the congulated gum adheres and forms a disc, varying in size according to the number of scores it is rolled in. These discs are then boiled in water and made into balls, and sold by the collectors to the persons who export it to Singapore and Penang. The gutta is at first white, but soon changes to pink, and finally to a brownish red. The amount yielded by a single tree about 100 feet high, and whose age was estimated to be over a 100 years, was 2 lbs. 5 ozs. of fairly clean gutta, valued by a Malay dealer at 3s. 3d. per lb. The product, therefore, of the whole tree is worth only 7s. 6d. Other species of the gutta tree in the Straits Settlements are (1) *Getah toban putch* (white), (2) *Getah toban sutra* (silk), (3) *Getah toban chayas* (liquid), and (4) *Getah toban simpor.* It is stated by the director of the botanical gardens at Singapore, that there are over 92 species altogether on the peninsula.

VELVET AND SILK INDUSTRY OF CREFELD.

The following extract from the report of the Crefeld Chamber of Commerce on the local velvet and silk industry is taken from the *Board of Trade Journal*:—

"The trade in velvet has fallen from £1,998,000 in 1890 to £1,401,000 in 1891; this is the lowest figure in the statistics since distinction has been made between the production of velvet and that of silk. The year 1891 will therefore be the worst that the velvet industry of Crefeld has experienced; it is inferior by £100,000 and £75,000 to the notoriously bad years of 1888 and 1889. The number of looms employed in hand weaving has fallen from 6,920 in 1890 to 3,351 in 1891, while there were 14,438 in 1887. There were 2,907 machine looms working in 1890, and 2,425 in 1891, a fact which indicates an important restriction in production. The velvet factories only paid £202,000 for labour in 1891, against £303,900 in 1890. This explains the great misery in the weavers' districts of the Lower Rhine, for this diminution in wages has been chiefly in respect of home industry. The diminution in the production of velvets is distributed as follows:—£275,000 less for the German market, £150,000 for England, and £150,000 for extra-European countries. This latter result may be partly attributed to the large consignments made to the United States in 1890, in view of the enforcement of the McKinley tariff, and further, to a certain extent by a change of fashion. The production of silk and half-silk tissues was valued at £2,430,000 last year, against £2,650,000 in 1890, and £2,800,000 in 1889. Beyond the dearness of the raw material, fashion is also responsible for this falling off. This branch of the weaving industry only employs 11,650 hand-looms, against 14,263 working in 1890. On the other hand the number of machine looms working has increased by about 100. The German markets has absorbed nearly half of the manufactured products. Although production diminished last year by about 8 per cent. as compared with 1890, the quantity of raw silk used has increased, because a greater quantity of tissues composed entirely of silk has been woven than previously. This is shown by the fact that there were consumed 439,000 kilos. less in 1891 than in 1890, and that a hand-loom has produced on an average £138 worth of tissues in 1891 against £131 in 1890. Wages aggregated £488,000 in 1890. Home industry received £72,000."

Chicago Exhibition, 1893.

MEETING OF THE ROYAL COMMISSION.

A meeting of the Royal Commission was held on Tuesday, 26th July. Present: The Attorney-General, Q.C., M.P., in the chair; Sir Frederick Abel, K.C.B., D.C.L., D.Sc., F.R.S., Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D., Major-General Sir Owen Tudor Burne, K.C.S.I., C.I.E., Alfred Carpmael, Michael Carteighe, R. Brudenell Carter, F.R.C.S., Sir George Hayter Chubb, Lord Alfred S. Churchill, B. Francis Cobb, Prof. James Dewar, M.A., F.R.S., James Dredge, Francis Elgar, LL.D., Sir Edward Harland, Bart., M.P., Walter H. Harris, John Biddulph Martin, John Fletcher Moulton, Q.C., F.R.S., John O'Connor, William Henry Preece, F.R.S., Professor William Chandler Roberts-Austen, C.B., F.R.S., Sir Albert K. Rollit, M.P., Sir Owen Roberts, M.A., F.S.A., Sir Saul Samuel, K.C.M.G., C.B., with Sir Henry Trueman Wood, M.A., Secretary.

AGRICULTURAL COMMITTEE.

A meeting of the Agriculture and Food Products Committee was held on Monday, 25th inst., at 12, Hanover-square. Present: Earl of Faversham in the chair; R. Bannister, Earl Cathcart, Major Craigie, Dr. J. H. Gilbert, F.R.S., Colonel Sir Nigel Kingscote, Lord Moreton, G. H. Sanday, John Thornton, Dr. J. Augustus Voelcker, C. W. Wilson, Sir Jacob Wilson, and Ernest Clarke, honorary secretary.

ELECTRICITY COMMITTEE.

A meeting of the Committee for Electricity was held on Thursday, 21st inst. Present: William Henry Preece, F.R.S. (chairman); Professor W. Grylls Adams, M.A., D.Sc., F.R.S., Colonel R. T. Armstrong, C.B., R.E., Professor W. E. Ayrton, F.R.S., Professor James Dewar, M.A., F.R.S., Major-General E. R. Festing, F.R.S., J. E. H. Gordon, M.Inst.C.E., David Edward Hughes, F.R.S., W. M. Mordey, Mark Robinson, C. E. Spagnoletti, Professor Silvanus P. Thompson, D.Sc., F.R.S., Major-General C. E. Webber, C.B., with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

TRANSPORTATION COMMITTEE.

A meeting of the Transportation Committee was held on Thursday, 21st inst. Present: Sir Douglas Galton, K.C.B., F.R.S. (chairman); Sir Nathaniel Barnaby, K C.B., James Dredge, and Professor Elgar.

DETERIORATION OF MATERIALS.

The following Special Decision of the United States Treasury Department relative to deterioration or destruction of materials imported for exhibition, has been received by the Secretary to the Royal Commission:—

Treasury Department, Office of the Secretary,
Washington, D.C.,
June 2nd, 1892.

Hon. George R. Davis, Director-General, World's Columbian Exposition, Chicago, Ill.

Sir,—During our recent conversation at the Department allusion was made to the question of the dutiable character of those articles imported for exhibition at the Exposition, in regard to which the practical demonstrations which are required to show their use and properties will result in their destruction, and which, therefore, cannot be exported at the close of the Exposition, as is contemplated by the law and regulations concerning ordinary importations of articles for the Exposition. In order to avoid any misapprehension of the Department's position, I will now state that a careful distinction will be made between articles which are imported for use by the authorities of the Exposition in the general economy of the same, and are therefore liable to duty, and similar articles which are imported solely for exhibition, although the consumption or destruction of the latter may be incidental to the demonstration of their fitness for the purpose for which they are intended. Articles of the latter class are entitled to free entry and need not necessarily be withdrawn from constructive warehouse "for consumption" before being thus applied, it being held in regard to them that the words "for exhibition" include such use as is implied in the practical application to them of mechanical or scientific forces to produce motion or chemical action.

Satisfactory evidence of such consumption or destruction will be accepted at the close of the Exposition as authority for closing the Customs accounts of the respective articles.

Of course, due vigilance will be required of Customs officers to guard against any misconstruction or perversion of this liberal interpretation of the Act of April 25th, 1890, relating to the Chicago Exposition.

Respectfully yours,

(Signed) O. L. SPAULDING,
Acting-Secretary.
Per J. M. C.

THE WORLD'S CONGRESS AUXILIARY.

The following letter from the American Minister to the Secretary of State for Foreign Affairs has been forwarded to the Royal Commission :—

The Most Honourable the Marquis of Salisbury, K.G.

Legation of the United States.
London, July 16, 1892.

MY LORD,—I have the honour to acquaint your Lordship that the Department of State of the United States is in receipt of a letter from Mr. Charles C. Bonney, president of the World's Congress Auxiliary, in which it is stated that, in pursuance of the course indicated in the original announcement of the World's Congress Auxiliary, which was transmitted to your Lordship in my note of February 2, 1891, with the Act of Congress approved April 25, 1890, and the President's invitation of January 14, 1891, extending to all foreign Governments a cordial invitation to participate in the World's Columbian Exposition, to be held in Chicago in 1893, the work of the World's Congress Auxiliary has been organised, to the present date, in 16 Departments and more than 100 General Divisions in which Congresses are to be held.

The preliminary organisations of these Congresses are contained in the preliminary publications of the Auxiliary, copies of which are herewith transmitted, and the accompanying printed pamphlets amply disclose the plans, aims, objects, and purposes of the Congresses.

I am therefore instructed to say to your Lordship that it is especially desired by my Government that the largest practicable participation of foreign peoples and Governments in the whole series of these important Congresses may be secured, and that it is particularly requested that a convenient number of the most eminent representatives of the various departments of human progress be selected as delegates to attend the respective Congresses, by or under the direction of each of the foreign Governments, in addition to those who will come as the representatives of the leading institutions and societies of the different countries. Such a co-operation on the part of other Governments will, it is confidently believed, tend in the highest degree to promote, strengthen, and extend those fraternal relations and mutual benefits which may now justly be regarded as the supreme object of international intercourse, and as involving a higher civilisation, and a broader human progress.

I have, therefore, the honour of communicating this supplementary invitation to Her Majesty's Government, and, in doing so, I venture to call your Lordship's attention to the brief intervening period, and to express the earnest hope that Her Majesty's Government will be disposed to give the necessary co-operation, to ensure the adequate participation of Her Majesty's subjects in these interesting Congresses.

I am directed also to say that, on receipt of the names of such delegates as may be selected to attend these several Congresses, suitable communications will be promptly forwarded to them.

I have the honour to be,
With the highest consideration,
My Lord,
Your most obedient humble servant,
(Signed) R. LINCOLN.

Proceedings of the Society.

CANTOR LECTURES.

MINE SURVEYING.

By BENNETT H. BROUGH,
Assoc.R.S.M., F.G.S.

Lecture III.—Delivered April 11, 1892.

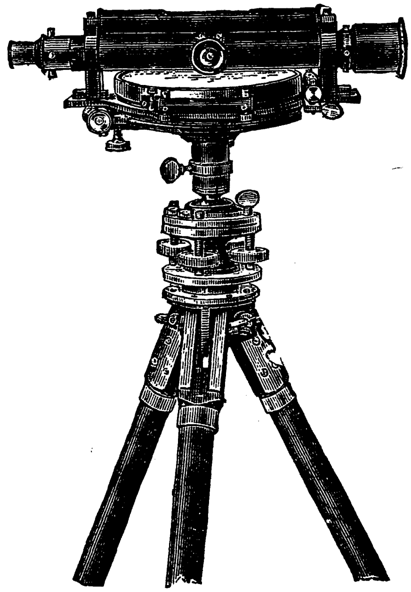
In the last lecture we considered the various instruments that are used for obtaining the data requisite for the construction of a mine plan. For the determination of the difference in height of the various points, with a view to preparing the section or vertical projection of the mine, we must have recourse to a system of levelling. The spirit-level is the instrument commonly used. The common bubble-tube is attached to a telescope in such a manner that it indicates the horizontality of the optic axis. This instrument, supported on a tripod stand, is placed midway between the two points whose difference in level is required. A graduated staff is held vertically on the first of these points, and, with the bubble remaining at the centre of its tube, the telescope is turned towards it, and the height at which the optic axis intercepts the staff is read off. The staff is then removed to the second point, and held

vertically. The telescope is directed towards it, and the height intercepted is again read off. The difference between the two readings indicates the difference of level between the two points. When the distance is too great, or the ground too much inclined for the difference of level to be determined by one operation, the process has to be repeated, the difference of level of each two successive points being determined in the way described. Thus, if the ground is irregular, we have a series of rises and falls; and regarding the former as positive, and the latter as negative, we find that the difference of level between the two end points is obtained by calculating the algebraical sum of the rises and falls. When a section of the ground is to be drawn, the distances between the several stations must be carefully measured, and the vertical distances are calculated above an assumed level line, known as the datum. Fixed points of reference, termed *bench-marks*—the levels of which are known—are selected at intervals along the line. In the Ordnance Survey of this country, the bench-marks, having the familiar form of the broad arrow, are generally chiselled on some permanent stone slab or wall.

Accurate levels are as essential as accurate plans; but, unfortunately, in many mines where very satisfactory survey work is done, there is an absence of a carefully conducted system of levels. Many colliery plans contain no levels, and the relative elevations of different parts of the workings can only be obtained approximately from the dip of the seam and by measuring the depths of shafts. Several large collieries are accurately levelled; but the elevations at each colliery are based upon a separate datum. What is required is a carefully connected system of elevations based upon a common datum, preferably that of the Ordnance Survey, the level of the sea. For continuing the Ordnance levels into the workings, Mr. J. A. Ramsay has made a very practical suggestion. In the Ordnance bench-mark, the broad arrow points upwards to a horizontal line. In order to make a distinction, he suggests that as soon as the levels become lower than the datum-line or sea-level, the broad arrow should be reversed. The levels obtained in this way may be written upon the plan in plain figures at particular points in the main roads, and when necessary may be continued into the face of the workings.

There are many forms of spirit-levels in use, and the chief of these were fully described in Mr. W. Mattieu Williams's course of Cantor lectures in 1879. For underground use, a simple level is that made by Messrs. E. T. Newton and Son, in which the telescope fits on to the plate of the ordinary dial (Fig. 11). The German levels for mining work are usually supported on three levelling screws, and in some cases the instrument is so arranged that the telescope can be moved up and down about 18°. The tripod enables any of the legs to be lengthened to 4 feet 3 inches or shortened to 2 feet 3 inches. This arrangement offers great advantages in levelling in the mine and on steep mountain slopes. Sometimes the tripod

FIG. 11.

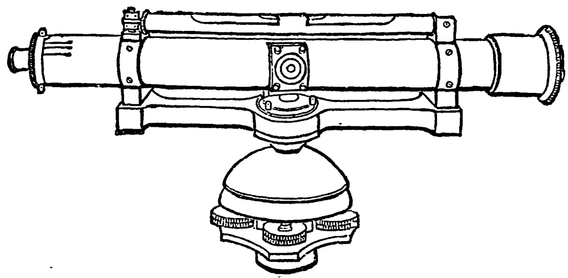


is replaced by a wrought-iron arm which can be screwed into the mine timber. This is specially useful for levelling in shafts.

Several of the latest patterns of level are exhibited to-night, and you notice that the construction of these instruments has been brought to a high degree of perfection. The 16-inch Dumpy level (Fig 12, p. 824), made by Davis and Son, shows the application of the Hoffman tripod head to instruments of this class. Stanley's new level presents many features of novelty. It has a very rigid stand, the top of the head being in one casting, and not built up. A tribrach stage instead of four parallel screws, which permits the instrument being used on a wall without the legs, prevents all possibility of straining the centre, and allows of the

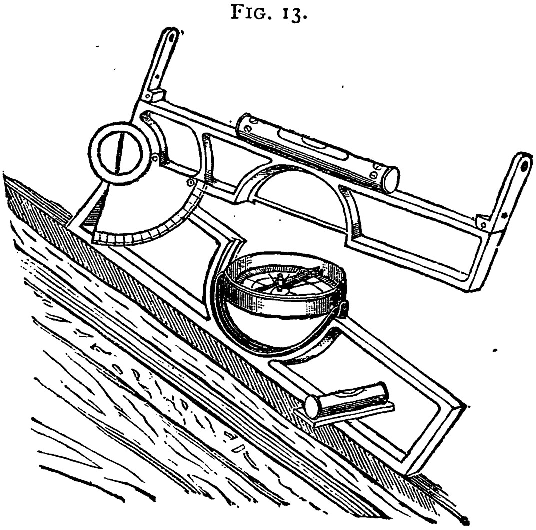
employment of an extra sensitive bubble. Instead of webs—which are a constant anxiety—platinum-iridium points are substituted. These do not cover up the divisions on staff, and neither rust nor break, are permanent in all climates, and allow of any dust being brushed off with a camel-hair pencil without interfering with the adjustment. The cap of the telescope is sighted and divided to 30° for taking rough inclines. The levelling staff generally used is that invented by Thomas Sopwith in 1838. It is telescopic, opening

FIG. 12.



from 5 feet 4 inches to 14 feet, and is clearly divided into feet, tenths, and hundredths. For levelling in mines, the staff is made 2 feet 3 inches in height, opening out to 5 feet or 8 feet. Mr. Stanley has designed a useful mining staff, which is made in lengths of 18 inches, like a folding rule. It opens out to 9 feet, and, when closed, is 20½ inches long. Messrs. Davis and Son make a mine staff, designed by Mr. G. L. Jee. It is constructed

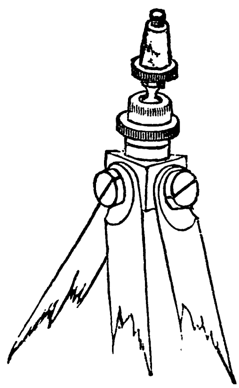
FIG. 13.



in three lengths, sliding one into the other, the bottom one, of three feet, being graduated in the usual way. The top of this length has a band attached to it, painted to continue the divisions upwards. This band passes over a roller attached to the top division of the staff, and is maintained at constant tension by a spring. By extending and clamping the lengths of the staff, any height, up to 9 feet, may be obtained.

Besides the spirit-level, other instruments are sometimes used for mine levelling. The aneroid barometer has been constructed so as to indicate a difference in a level of one foot, whilst there are various forms of clinometer that are largely used for exploratory work. A useful instrument of this class is the clinometer, designed by Mr. H. Louis, Assoc.R.S.M., which is made by Messrs. Davis in aluminium. It is a combined compass and a clinometer (Fig. 13), the compass

FIG. 14.



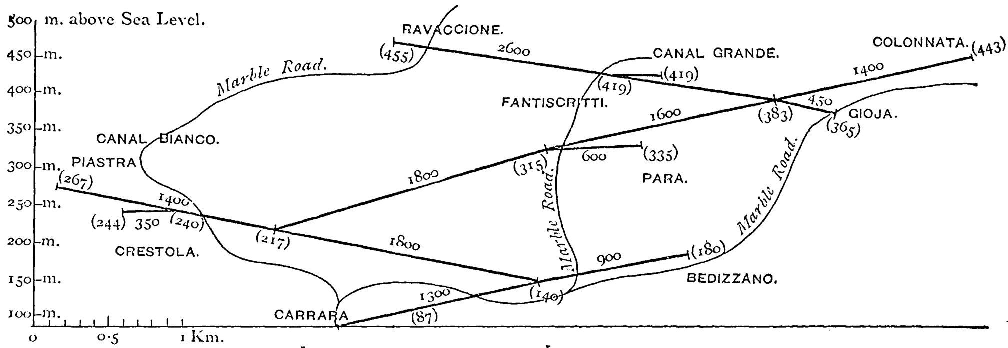
pivots being carried on a brass arc capable of revolving in the lower portion of the clinometer frame, so that the compass can be placed horizontally and read, regardless of the position of the lower limb. In this way, the dip and strike of strata, or the amount and direction of inclination of an inclined shaft, may be read simultaneously. The construction of the tripod for this instrument is shown in Fig. 14.

In connection with levelling operations underground, it is frequently necessary to

measure the depths of shafts. In perpendicular shafts the depth may be measured direct by applying rods, chains, or steel bands to the timbering of the shaft; or the winding rope may be used. The latter may, however, occasionally give rise to error. An example of this occurred in California, where a party of capitalists undertook to pay $5,000 for half of a certain mine if the owners would continue the shaft down 150 feet. After a short interval, it was announced that the shaft was complete, and one of the purchasers went to measure it. Arrived at the mine after a long and rough ride, he found the shaft very dirty, and badly provided with ladders; so being stout, he determined not to risk his neck, but to measure the depth by means of the windlass rope. With a measuring tape he found the soiled portion to be over 150 feet in length, and he returned home satisfied. Part of the purchase money had been paid, when another of the purchasers went down, and found the shaft just 80 feet in depth, the ingenious vendor having carefully soiled the additional length, relying on the uninviting appearance of the shaft deterring the purchasers from making a direct measurement.

In surveying and levelling in the shafts of the Lehigh Valley Coal Company, in the United States, a new form of plummet has recently been adopted. It consists of a vertical core 12 inches long, with eight radiating flanges 9 inches high by 3 inches wide of ¼-inch metal. At the bottom there is a circular disc acting as a web. This plumb-bob weighs 20 lbs., and has a surface area of about 630 square inches. An ordinary bob of equal weight would have a surface of 90 square inches. In a dry shaft, 500 feet deep, this form of plumb-bob will settle, under ordinary conditions, in about one hour instead

FIG. 15.



Longitudinal scale: $\frac{1}{50,000}$ *Vertical scale:* $\frac{1}{5000}$ *Lengths and altitudes in metres.*

of in five or six hours, as is the case with the older form.

In connection with mining work, there are numerous cases illustrating interesting applications of levelling. For example, the railway at the Carrara marble mines, owing to the peculiar nature of its alignment, presents several striking features. The Carrara district is situated between Spezzia and Leghorn on the Mediterranean sea-board. The marble strata cover an area of 80 square miles, and reach in places the enormous depth of three-quarters of a mile. The mines, some of which were worked by the Romans as early as 200 B.C., are surface workings at an altitude of 700 to 3,000 feet above the sea level, the aggregate annual output being about 205,000 tons. The railway, which was described in detail by Dr. C. B. Sheibner, in a paper communicated last year to the Institution of Civil Engineers, has a total length from the sea to the mines of 16 miles. The loading stages of the principal mines are situated at altitudes varying from 876 to 1,492 feet, and at short distances apart, but are separated from each other by steep ridges rising up to 3,000 feet above the sea-level. Owing to the rapid rise of the ground it was found impracticable to send a separate branch up to each mine from Carrara, following the ancient watercourses now occupied by the bullock-cart roads; and rope-traction on inclined planes would have involved placing a stationary engine of 150 horse-power at each of the nine mines. Hence the only practicable alignment with grades of 4 to 6 per cent., to be worked by ordinary adhesion, was that of a series of reverse stations shown in Fig. 15.

The grade of 4½ per cent. is fairly uniform throughout the ascent of 1,207 feet, from Carrara to the summit level at Ravaccione. It increases to 5 and 6 per cent. near the

Colonnata terminus; and the two safety sidings near Miseglia and Tornone, have a grade of 7 per cent. The works throughout are very heavy, there being 15 tunnels, with a total length of 2·1 miles, and 16 bridges and viaducts; whilst the remainder consists entirely of cuttings and sustaining walls from 16 to 46 feet in depth. This was rendered necessary, not only by the nature of the ground and the high cost of land adjoining the mines, but also by the loose masses of marble refuse, which could only be avoided by extensive tunnelling.

Another branch of engineering, in which the application of levelling is of great importance, is the setting out of aërial wire ropeways. The importance of this mode of transport in the development of mineral resources is known to every mining engineer. As a case in point, the rich iron ores of the Sierra de Bedar, in southern Spain, would probably have remained untouched to this day but for an aërial wire ropeway, 9¾ miles in length, which connects the mines with the shore of the Mediterranean, near the town of Garrucha, and which affords cheap transport to the point of shipment. An ordinary railway would have cost £100,000, whilst an aërial ropeway could be built for about one-quarter of that sum, an outlay which left a satisfactory margin for profits on the sale of ore.

In the older systems of ropeways, one endless rope is employed, serving both as carrying rope and hauling rope for the buckets. Many examples of lines of this class can be seen in the Bilbao iron ore district. The characteristic of the modern or Otto system consists in the employment of two ropes—a heavy fixed carrying rope and a light travelling hauling rope, the buckets being fitted with special devices for gripping the latter. With ropeways of this class loads of 20 cwt. can be carried, so that as much as 800 tons may be transported in a day of 10 hours.

The most important Otto ropeway yet constructed is the one I have already alluded to for the transport of iron ore at Garrucha. The line is divided into four independent sections, the two first being driven by a 30 horse-power engine, and the two last by a 70 horse-power engine. The greatest span (Fig. 16, p. 827) of the line is 918 feet, the height above the valley being 164 to 196 feet. The steepest gradient is 1 in 2½, and the tallest standard is 118 feet. The guaranteed capacity of the line is 400 tons per day of 10 hours. Since the commencement of 1890, the line has been worked in two shifts of 8 hours, and no less than 900 tons per day have been transported to the coast. Despite many difficulties, the line was surveyed, erected, and ready for work within ten months.

Another important Otto wire ropeway is that constructed by Messrs. Commans and Co. for the Sheba gold mine in the Transvaal (Fig. 17, p. 828). This is 2¾ miles in length, and has a capacity of 150 tons per day of 10 hours. The maximum incline is 1 in 1·6, and the greatest span 1,480 feet. Although the ropeway is usually considered to be quite a recent invention, an old engraving (Fig. 18, p. 828), dated 1641, in the possession of Mr. Pohlig, of Cologne, shows an aërial ropeway with endless rope, at work in the construction of the fortifications of Dantzig.

In making the preliminary survey for an Otto wire ropeway, there are several points to which attention should be paid. The terminal points of the line should, whenever possible, be so placed that the ropeway joining them shall be in a straight line, as each turn increases not only the amount of construction necessary, but also the cost of working, as it necessitates the erection of a complete station. For lines of more than 3½ miles in length, one or more intermediate stations must be erected, as greater lengths than this cannot be worked with one hauling rope. At the stations the line can form any desired angle. The points selected for the supports for the bearing-rope should be marked on the ground by wooden pegs distinctly numbered, and should be shown in the section drawn. The distances between the supports should be 50 yards, when 50 to 100 tons are transported in 10 hours, 40 yards for 100 to 600 tons, and 35 yards for amounts above 600 tons in 10 hours. This rule may be neglected in crossing roads, in which case one support should be at the side of the road, and it may be neglected when this rule would necessitate the support being placed in a narrow valley or hollow, in which case, in order to avoid unneccessary height, the post may be moved. For crossing valleys and rivers, spans of 350 yards may exceptionally be employed, when supports are impossible, or would exceed 35 yards in height. In crossing roads, cross-sections must be made in order to give the requisite data for the erection of a protecting bridge, and cross-sections must be taken at every point selected for a station.

Marshy sites must be avoided as far as possible; but in cases where this is out of the question, the surveyor must determine the

depth to the solid ground. He frequently, too, has other difficulties to contend with. For example, in making the preliminary survey for an Otto wire ropeway in one of the West Indian islands, I found that the work was rendered more complicated by the dense tropical vegetation. It was impossible to see the two ends from any point in the proposed line, and it was consequently necessary first to make a traverse survey, and then to set the

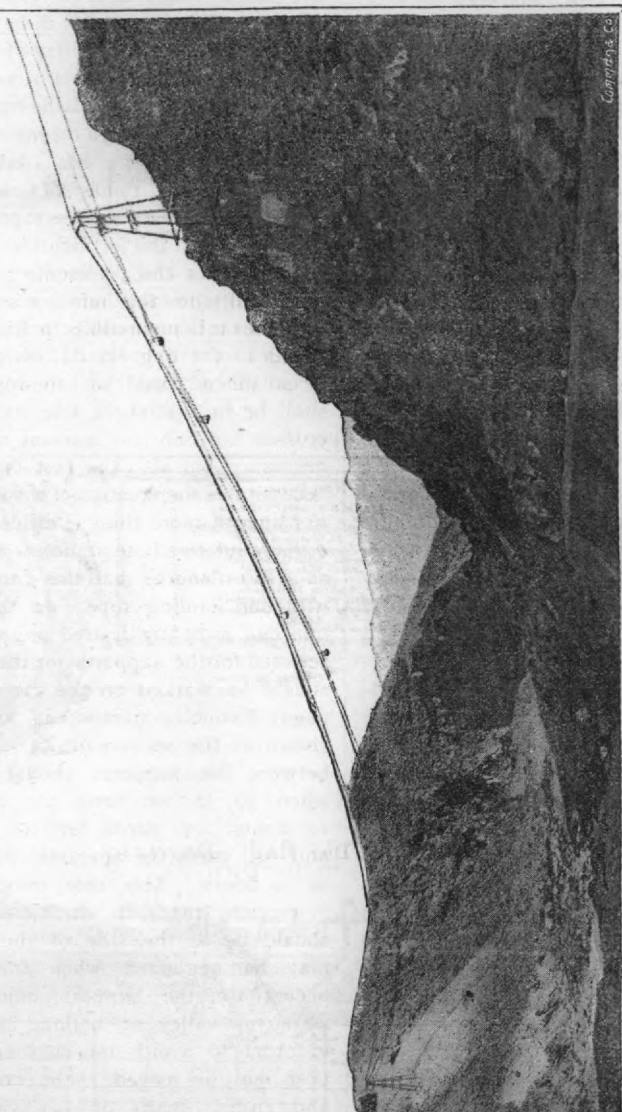


FIG. 16

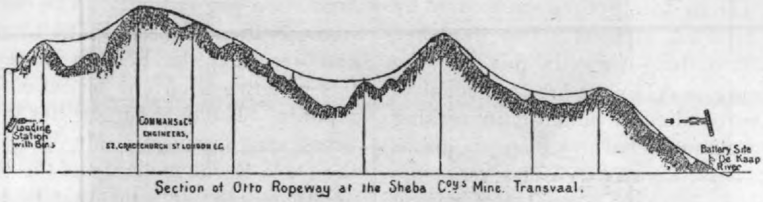
LARGE SPAN, GARRUCHA WIRE ROPEWAY.

line out from the calculated co-ordinates, a path being cut for the line of levels through the jungle.

The hydraulic mining ditches of California afford some interesting examples of levelling successfully conducted in the face of great difficulties. Hydraulic mining consists in the disintegration of auriferous gravel deposits by propelling a heavy jet of water under pressure upon the bank, and in washing the gravel

down through sluices in which mercury is distributed. The gold forms an amalgam, and is thus caught. This method of mining was introduced in California in 1856, although its origin is much older, as Pliny describes a system of hydraulic mining in Spain, which resembled in many respects the modern method. Hydraulic mining has given rise to an extensive system of artificial reservoirs in the Sierra Nevada for the storage of

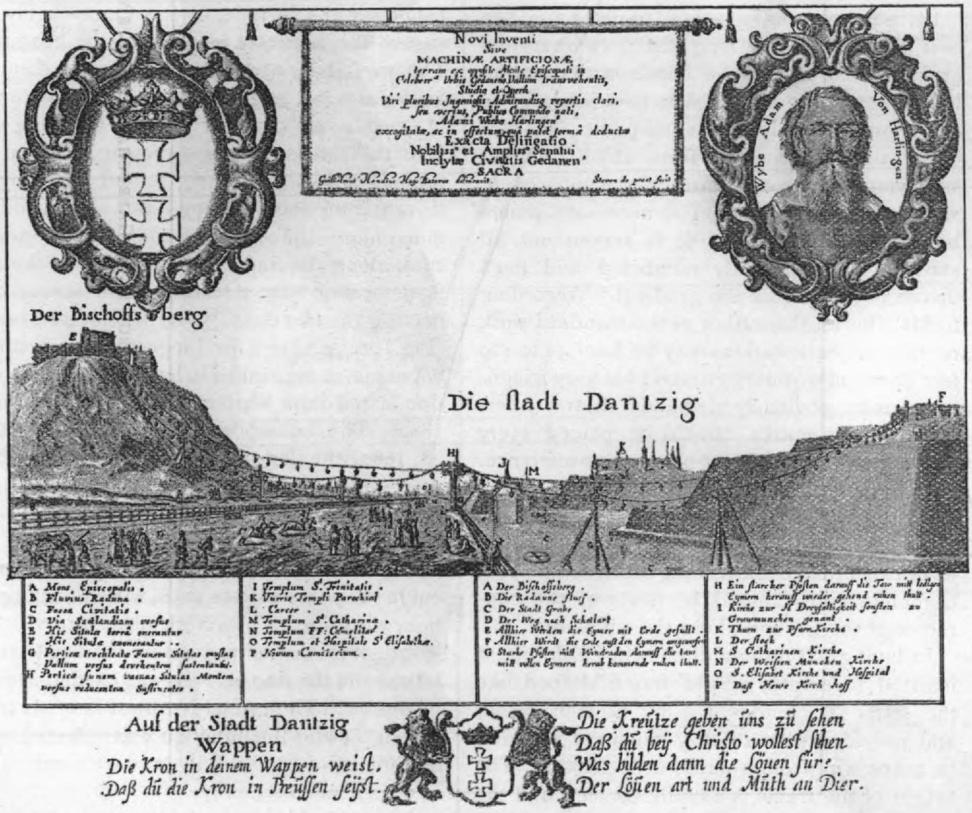
FIG. 17.



Section of Otto Ropeway at the Sheba Coy's Mine. Transvaal.

water, and to the construction of artificial water-courses to convey the water thus stored to the scene of mining operations. The setting out of these canals at a grade of from 4 to 20 feet per mile, over deep gorges and along precipitous cliffs, presents problems of great difficulty to the mine surveyor. In many places it is impossible to find room along the sides of the great cañons for miles to excavate a canal or to rest a conduit or

FIG. 18.



"flume," as it is locally termed. The bracket flume of the Miocene mine is a marvellous example of engineering skill. Here, in order to obviate the erection of a trestle 180 feet in height, the water is conveyed in a wooden flume—4 feet wide and 3 feet deep—round a cliff 350 feet in height. The flume is suspended upon brackets made of T-rails, fixed into holes previously drilled in the vertical cliff. In another place, in the line of this ditch, is a

piece of trestlework 1,088 feet long and 80 feet high. Again, the Blue Tent Mine has a ditch running for a distance of six miles along the face of a cliff, over which the surveyors had to be suspended by ropes 1,000 feet above the bottom of the gorge, in order to establish the line of the flume.

In other places deep gorges are crossed by means of inverted siphons. The Cherokee ditch crosses a deep cañon in this way, the pipe sustaining a columnar pressure equal to 800 feet in perpendicular height. In making the crossing, 12,000 feet of 38-inch pipes, 3-8ths inch in thickness, were used. A few years ago there were in California 6,000 miles of mining ditches, their estimated total cost being £3,000,000. Some of them have been built at a cost of £5,000 per mile. The cost, too, of keeping them in repair is very considerable, as the hydraulic miner has constantly to contend with the elements—frost and flood, ice and snow, wind and rain.

In the preliminary survey, to determine the best situation for a long ditch, comparative observations should be made with aneroid barometers, care being taken to determine the elevations, not only of the end points, but also of intermediate points, from which different surveying parties can start on the subsequent setting out of the line. The necessary points being established, the line is staked out, all stations being properly numbered and pegs driven in to indicate the gradient. According to Mr. Bowie, the author of the standard work on this subject, stations may be from 50 to 100 feet apart on ordinary ground; but very irregular country obviously demands shorter intervals. Bench-marks should be placed every quarter or half a mile for convenient reference. All details of tunnels, cuttings, and depressions, which require pipes or flumes, should be worked out in full, a work in which the hand-level can often be advantageously employed. Complete notes should be made of the character of the ground along the whole line.

In laying out mining ditches in California, it is usual to employ a light frame shaped like the letter **A**, made of $\frac{1}{2}$ by $1\frac{1}{2}$ inch wood, and provided with a heavy plummet hanging on a fine wire from a notch at the apex. The height of the frame is usually six feet, and the base ten feet. To commence, one end is placed on a level piece of ground, and the other end is raised or lowered until both ends are level, and the plumb-line marks the same position on the cross-bar, if turned completely round. The grade for the proposed mining ditch being decided upon, say half an inch in ten feet, a half-inch piece of wood is placed under the rear end of the frame, and the point indicated by the plumb-line is marked on the cross-piece. One man then holds the frame, while another lifts the front end until the plummet coincides with the mark, he then drives in a peg in front. The rear end of the frame is then placed exactly where the front end was, and the process is repeated. In this way the ditch can be set out with great rapidity. The only danger lies in getting the wrong end foremost. Mr. W. J. Sharwood, the De la Beche medallist of the Royal School of Mines, 1887, tells me that he has seen one ditch that was actually dug for three-quarters of a mile, with the apparent object of carrying water up-hill.

In surveying and levelling tunnels, the difficulties encountered by the surveyor are frequently considerable, great care being necessary to transfer the centre line, established on the surface, to the tunnel below, to ensure the accurate meeting of the headings. The work has, of course, to be carried on by artificial light, and the atmosphere in a tunnel in course of construction is anything but favourable to accurate surveying. When the tunnels are of great length, and can only be driven from the two ends, the setting out is much more difficult than when shafts can be sunk along the line. The direction of the axis is determined by a triangulation survey connecting the two ends. The St. Gothard tunnel (Fig. 20, p. 830), the longest railway tunnel yet made, is nine miles in length. Its construction lasted from September, 1872, to February, 1880. The holing was effected on February 28, 1880, the length being 25 feet less than was expected. The error in level was 1·97 inch, and the error in alignment was 12·99 inches.

The Mont Cenis tunnel (Fig. 19, p. 830) was set out in the years 1857 to 1858, without triangulation, with the aid of a high observatory. The length of the tunnel was determined by triangulation, and the line of levels was carried over the mountain. The tunnel is upwards of six miles in length, and the junction was effected without any error horizontally, and with only a foot of divergence vertically.

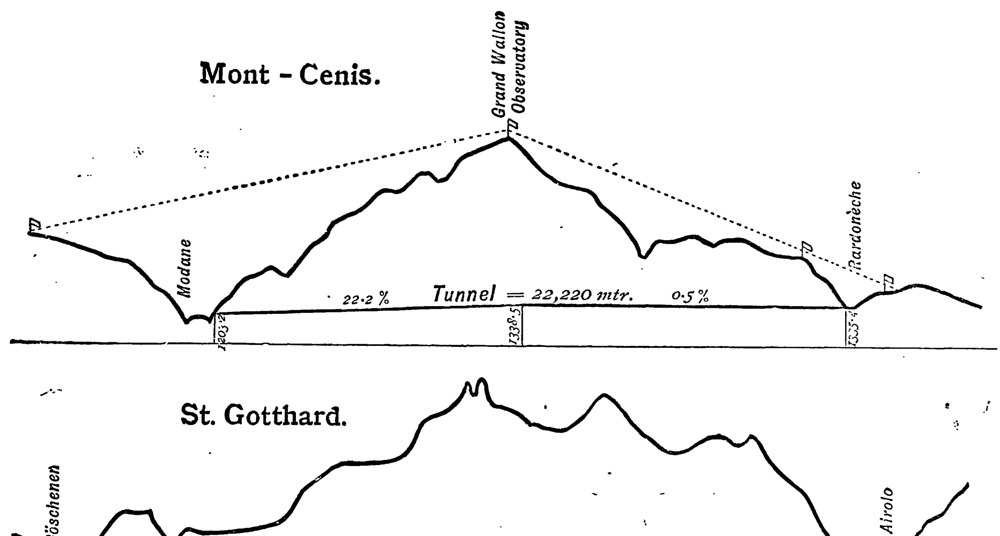
A remarkable example of successful holing was afforded by the Ernst-August adit-level, the great subterranean canal in the Hartz mountains, communicating with a main winding shaft at the dressing-floor, and serving both as a means of transit for the ore, and as

a drainage level for the mines. This great adit, one of the largest in the world, was begun in 1850, and finished on July 22, 1864. It has a total length of 25,956 metres (15½ miles), and was driven from bearings and distances calculated from the results of a survey, made with extreme accuracy by the theodolite and level, the length of theodolite survey for each holing averaging 12,000 feet. The error at the nine holings averaged 9 inches.

Remarkably accurate results in tunnel alignment were recently obtained in the Croton Aqueduct at New York. In one case, the starting points of two headings were 6,400 feet apart, the one 270 feet and the other 353 feet below the surface. The diameter of the heading was 16½ feet. The direction was obtained by means of two plumb lines, 16½ feet apart, let down each shaft. When the two headings approached each other, the final connection was made by two drills meeting in the same hole from opposite sides of the rock, and after the blast had been fired, it was found that the error in level was 0·014 foot, and that in alignment, 0·09 foot.

In the construction of Division No. 6 of this aqueduct, Mr. F. W. Watkins, the engineer in charge, found that the centre-line wires were very difficult to distinguish, as the cross-hair of the telescope and the two plummet lines appear so nearly alike. He was, therefere, induced to devise an illuminated slit apparatus to replace the wires at the bottom of the tunnel. This instrument consists of

FIGS. 19 AND 20.



two vertical strips of brass (3 inches in height) attached to separate horizontal bars moving in guides, and provided with a tangent-screw motion, by which one or both could be moved right or left and the vertical aperture between them made as small as desired. One of these instruments was screwed to a plank-bracket, close behind each plummet wire, and so placed that the farther one could be seen through the telescope in line just above the other. When these slits were adjusted so as to be directly behind the plummet wires, the latter were removed, and lights placed behind the slits. In this way two fixed and illuminated lines were substituted for the wires. The results of tests of the alignment effected in this way show that the accuracy of the surveys was very remarkable.

Taking cross-sections, for measuring the areas and quantities of excavation in tunnel work, is best done by measuring the irregularities of the contour of the section, by angles and distances, from some point in the vertical plane through the axis of the tunnel. For the Croton aqueduct tunnel, where sections had to be made every 10 feet for over 30 miles of tunnel, a convenient instrument was designed by Mr. A. Craven. This instrument, known from its yellow disk of varnished wood as the sunflower instrument, consists of a light wooden tripod

with extensible legs, a shifting top, ball and socket joint, and levelling screws. A vertical brass tube slides through the socket, and carries at its top a wooden graduated disk, 18 inches in diameter. An arm revolving on a central socket traverses the face of the disk, and a wooden measuring rod, 14 feet in length, is placed on this arm, and slid out to touch the surface of the tunnel, the end of the arm at the same time indicating the angle from the vertical. The measuring rod tapers from 2 inches to ½ inch in width, and is graduated in feet and tenths from the smaller end. In order to ensure the cross-section being taken at right angles to the axis of the tunnel, the disk is provided with a small sighting tube perpendicular to its face. The measurements are recorded in the field-book, and the areas of the cross-sections are determined by calculation, or by the planimeter.

When the difficulties of the task are duly considered, it is probable that the accuracy of the work at the Hoosac tunnel has never been equalled. This tunnel passes through the Hoosac Mountain range in Massachesetts, and is 25,031 feet in length. The tunnel was driven from the two ends, and also from a shaft 1,028 feet deep sunk in the valley between two mountains in the line of the tunnel. On the east side, the headings met at a distance of 1,563 feet from the shaft, and 11,274 feet from the eastern end, the lateral error being 0·025 foot, and the vertical error being 0·23 foot at the point of junction. Proceeding westward, the tunnel extended 2,056 feet from the shaft before meeting the excavation on the western side, which was 10,138 feet from the west entrance. The holing showed that the error of alignment was 0·045 foot. The alignment in the central shaft was obtained by two plumb-bobs 25 feet apart.

In New South Wales, a very successful alignment was effected by Mr. T. W. Keele in the construction of the Nepean tunnel, a conduit for supplying Sydney with water. The tunnel is 23,507 feet long, and was driven from six shafts varying in depth from 210 to 324 feet. In each case the error on holing was extremely small, and after the tunnel had been pierced through daylight at one end was distinctly seen without the aid of a telescope from the other 4½ miles away.

Curiously enough, the oldest piece of tunnelling of which there is any written record was begun at the two ends, its construction being recorded in the oldest example of Hebrew writing known. The inscription, now known as the Siloam inscription, was discovered by some boys bathing in the Pool of Siloam, in Jerusalem, in 1880. It is cut on a tablet 27 inches square at the mouth of the tunnel, and, according to the translation of Professor Sayce, reads as follows:—

"[Behold] the excavation! Now this is the story of the tunnel: While the miners were still lifting up the pick towards each other, and while there were yet three cubits [to be broken], the voice of one called to his neighbour, for there was an excess in the rock on the right. They rose up—they struck on the west of the tunnel; the miners struck each to meet the other pick to pick. And there flowed the waters from their outlet to the Pool for a thousand two hundred cubits, and [three-quarters] of a cubit was the height of the rock over the heads of the miners."

From this inscription, it is evident that the tunnel was begun from the two ends. And this view is confirmed by the results of recent explorations. The Pool of Siloam is supplied with water from the so-called Spring of the Virgin, the only natural spring near Jerusalem, by this tunnel driven in the rock. According to Major Conder's survey, the tunnel is 1,708 feet long, or about 1,200 cubits of 18 inches. It does not, however, run in a straight line, and towards the centre there are two *culs-de-sac*, of which the inscription offers an explanation. We thus see that the engineering skill of the day was by no means despicable. Like the Mont Cenis tunnel, this aqueduct was begun simultaneously at the two ends, and, in spite of its windings, the workmen almost succeeded in meeting at the middle. They approached, indeed, so nearly to one another that the noise made by the picks of one party of miners was heard by the other, and the parting of rock was accordingly holed. This accounts for the two false cuttings now found at the centre of the tunnel, these representing the extreme points reached by the two parties before they had discovered that instead of meeting they were passing one another.

Though the inscription contains no indication of date, Professor Sayce is of opinion that the tunnel was made in the reign of Hezekiah, or possibly even in the time of Solomon.

With regard to the interpretation of the last line of the inscription that "three quarters of a cubit was the height of the rock over the heads of the miners," it is remarkable that the difference of height of the two channels at the point of junction is just 13 inches, or close upon three-quarters of a cubit. Unfortunately, however, the text is deficient just in the place

where the number occurs, and it may possibly indicate that the miners knew the thickness of the rock above them. In this case, the correct interpretation is probably 100 cubits, the average thickness of rock above the aqueduct. Several marks, evidently artificial, were discovered by Major Conder in the tunnel—square or triangular notches, measuring 1½ inches in width. These appear to have been used, like the peg and nail of the Cornish miner, to mark the end of a periodical survey, or else to serve as a guide in setting the contracts to the miner.

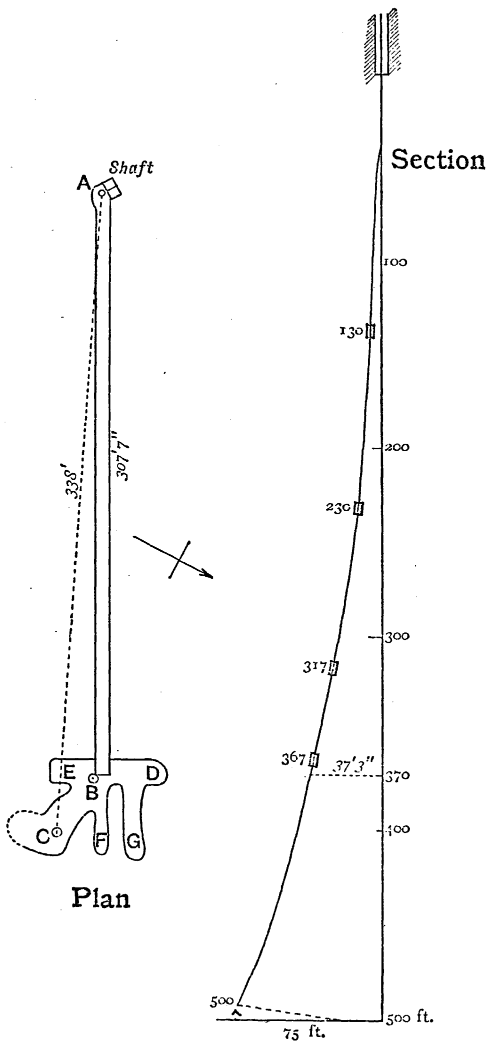
It is certainly remarkable that there should have been so slight a difference in level between the two portions of the tunnel. It would have been easy, by means of a plumb-line or a rude water-level, to preserve the level of the channel floor; but it is extraordinary that the two ends should differ by only a foot in level, considering that they were started independently.

Thus far we have considered the mapping of underground excavations that are accessible to the mine-surveyor. In exceptional cases, however, he is called upon to map excavations that are inaccessible; for instance, when it is required to ascertain the deviations in bore-holes. It has been assumed that the diamond drill always bores a vertical hole, even though passing through rocks of different hardness. Actual experience reveals an entirely different state of things, the deviations being sometimes so great as to render a bore-hole misleading.

A simple and effective method of surveying a bore-hole has been devised by Mr. E. F. Macgeorge, an Australian engineer. Clear glass phials, nearly filled with a hot solution of gelatine, and each containing a magnetic needle and a plummet in suspension, are encased in a brass protecting tube, and let down to the depth required. After remaining for several hours until the gelatine sets, the phials are withdrawn, and can each be replaced at the same angle as that at which they cooled by means of the congealed surface seen through the sides of the phial. Revolving the phial upon the part where the magnetic needle is seen embedded in the gelatine, until the needle is again in the meridian, obviously brings the phial to the same position as it had when its contents congealed. Thus the gradient and bearing of the borehole can be determined at measured intervals throughout its length. The recording instrument is somewhat similar to a theodolite, so arranged that, when the phial is placed in it, and adjusted by means of the imprisoned plummet and magnetic needle until it assumes the same position, both as regards inclination and azimuth, as it did in the borehole, the bearing can then be read off.

The invention was applied at the Scotchman's United Mine, at Stawell in Victoria,

FIG. 21 AND 22.



where the bore-hole was completely lost, huge chambers being cut in various directions before the bore-hole was finally found, by Macgeorge's method, nearly 40 feet away from its proper position. In the plan of the workings shown in Fig. 21, AB represents the exploratory level that failed to find the bore-hole at B—its theoretical position if the drill had gone straight. The subsequent

exploratory workings, BF, BD, BE, DG, were galleries 15 to 30 feet wide, and the miners were working hopelessly at G when Macgeorge's method was applied, and the bore-hole found at C, $37\frac{1}{2}$ feet away from its theoretical position, in a contrary direction to all previous workings. The explorations lasted twelve months, and cost £3,663. Had Macgeorge's method been applied before beginning the long level, it would have been merely necessary to direct the level along the line AC. The saving thereby would have been no less than £2,311. The section (Fig. 22, p. 832) shows the theoretical and actual paths of the drill; the deflection at 500 feet would be as much as 75 feet. Similar deviations have also been met with in other mining districts in Australia; several cases are recorded in the recently published report of the Royal Commission on the gold resources of Victoria. And it is probable that similar deviations are encountered in all districts where deep bore-holes are used.

A less satisfactory method of surveying bore-holes was adopted by Mr. G. Nolten (British patent, 1891, No. 4371). In the instrument employed for this purpose, the amount of deviation is etched upon glass by hydrofluoric acid, whilst its direction is found by means of a compass needle, clamped by the aid of a stop-watch, after sufficient time has been allowed for settling.

In these lectures I have attempted to trace the history of mine-surveying, to briefly describe to you the instruments used, and to give you some examples of mine-surveying practice. It must, however, be borne in mind that the mere listening to lectures or reading of text-books will never make a mine surveyor, The mechanical manipulation of the instruments can only be learnt under the personal supervision of a teacher, whilst the requisite skill for carrying out subterranean surveys must be obtained in the mine itself. Even by a skilled surveyor, no opportunity of testing the accuracy of his work should be neglected, and the first thing the beginner has to learn is to get rid of any trace of belief in his own infallibility.

In illustration of this lecture, Messrs. J. Davis and Son exhibited an 18-inch dumpy level with Hoffman joint, Jee's levelling staff, Louis's clinometer in aluminium, and a surveying aneroid. Mr. W. F. Stanley exhibited a large collection of improved dumpy levels, a mine levelling-staff, an Abney hand-level, and a surveying aneroid.

Miscellaneous.

THE TEAK FORESTS OF NORTHERN SIAM.

The Acting Vice-Consul at Bangkok, in his report just issued, says that the effect of the indiscriminate working and absence of conservancy is beginning to be very evident in the teak forests of Chiengmai and Lakhon. Teak saplings are cut down in large numbers for house posts, and even for making fences, and the clause in the leases forbidding the felling of small trees is disregarded. The consequence is, that in Chiengmai there is reason to fear that in five years' time the only teak left will be that which is too far from the water to be profitably worked; and in Lakhon the foresters complain that all the best trees have already been felled. The merchants who work teak in the Më Yom complain very much of the timber-stealing which goes on at Sawankalôk, the rafting station on that river. The stolen logs are often fired with kerosene to deface the hammer marks of the owners—the authorities do not appear to do much to keep the thieves in check. The present system of granting forest leases for three years only is very prejudicial to the interests of foresters. In many cases the leases are renewed when they expire, but a forester who is not fortunate enough to secure a renewal of his lease, may find that at the end of three years his logs are still lying in the forest, as it takes at least three years—generally much longer—from the time a teak tree is girdled, to fell the tree, lop off the branches, and drag and float the log out of the forest; and if the wording of the lease is strictly adhered to, all logs lying in the forests, and girdled trees, become the property of the owner of the forest as soon as the lease expires. Under these circumstances, a forester taking up a new lease is not likely to girdle many fresh trees, but will only fell the trees already girdled, and the lease being granted for such a short period he is not encouraged to make a large outlay of capital and labour in the first. Previous to the year 1888, the leases granted to British subjects were generally for a term of six years, but in that year the time was reduced to three years. This change was, it is said, due to the action of the Siamese Commissioners, by whom forest leases are ratified. The greater part of the capital with which the teak trade of the district of Northern Siam is carried on is British, and there are now three British firms engaged in the trade which have branches in Chiengmai or Lakhon, the Bombay-Burma Trading Corporation having established a branch at Lakhon in 1891. The Chiengmai forests on the Salween side are worked almost entirely with British-Indian capital brought from Maulmain. Some squared logs of teak are this year to be sent from Chiengmai to Bangkok as an experiment. The logs

are roughly squared in the forest before being put in the river, the advantages of sending such squared logs being that there is less weight to be dragged to water, payment of duty on the valueless part of the log is avoided, and the logs obtained are all sound. The axes used for felling teak have an iron head measuring ten inches by two inches. These axe heads were until recently all of native manufacture, but some of them are now imported from England.

INCREASE OF PUBLIC WEALTH IN PRUSSIA.

According to the tax-rolls of Prussia, the total population, in 1876, was 24,832,784, while in 1890 it was 29,087,933; there was thus an increase in population of 17·1 per cent., but the United States Commercial Agent at Mayence says that the number of persons in the population paying income-tax on incomes exceeding £150 increased 64·2 per cent.—from 571,975 to 939,072 persons—having risen from 2·3 per cent. of the entire population in 1876, to 2·9 per cent. in 1889. The total amount of tax derived from such incomes advanced from £1,552,727 in 1876, to £2,492,437 in 1889, or about 60 per cent., making an average annual gain of about 4·3 per cent. At the same time the number of persons entirely exempted from taxation of income increased nearly 16,000,000. In 1876 the number of persons exempted amounted to 6,369,836, or 26 per cent. of the population; in 1890, to 22,318,273, or 77 per cent., through extension of the amount exempted. The exemption is of all incomes under £45, but up to 1883 the exemption was only of those under £21. Prussia, during the years comprised between 1876 and 1890, has been growing in wealth and numbers, and the wages and salaries of its working population have in general experienced an increase, though counterbalanced, to some extent, by enhanced prices for the necessaries of life. The people of Prussia, in recent years, have taken a very large amount of German and other bonds and securities, through some of which heavy loss has been sustained, but, on the whole, they have been a source of profit and income to their holders. However that may be, the United States Commercial Agent says it cannot be denied that there has been an increase of the incomes of the Prussian people, taken altogether, since 1876, and especially of the wealthy classes. The number of persons in Prussia having taxable incomes amounted, in 1890, to 10,207,892, of which 6,769,660, or 23 per cent. of the population, were taxed. The taxable population, in 1876, was 8,467,076. By taxable population is meant, not subject to tax, but having incomes upon which the Legislature might impose taxes. The average income of an ordinary toiler in Prussia is estimated at £17 10s., and at £25 as the average income of a labouring household, which figures are said to be a mean computation between the highest and lowest estimates for this class of the population. The number of persons in Prussia enjoying an income of from £300 to £1,000 a year increased from 58,286 in 1876, to 91,512 in 1890, or 57 per cent., and the sum total of their incomes from £28,000,000 to £44,000,000, or a proportion of 60 per cent. In the case of incomes of from £1,000 to £5,000, the number of taxpayers increased from 7,501 in 1876, to 12,521 in 1890, and their aggregate incomes from £14,000,000 to £24,000,000, or about 66 per cent. The number of persons with incomes exceeding £5,000 rose from 532 in 1876, with an estimated aggregate income of £5,650,000, to 1,062 in 1890, with one of £11,000,000, or nearly double. The incomes from £100 to £300 also increased considerably during the period in question, but not in the same ratio as the larger ones. The number of persons estimated in 1876 to have an income of from £100 to £300 amounted to 384,248, with an aggregate income of £61,000,000, or £158 per head; in 1890, to 490,541, with £80,000,000 income, or £162 per head. Among this class of the population the increase in the number of taxpayers was 28 per cent., and in incomes 30 per cent., thus much behind the augmentation in the greater incomes. There has been a stricter estimate of incomes in Prussia in recent years, especially of the larger incomes, which fact swells the statistics to some extent, but an increase of general wealth has, it is said, been a still greater factor. This factor is better shown by the kingdom of Saxony, where everyone is required, under severe penalty for false declaration, to state his income. According to the official statistics of Saxony, the number of people assessed, and the aggregate amount of incomes in 1879 and 1888, were as follows:—Number of persons assessed in 1879, 1,088,002; in 1888, 1,327,771; aggregate income in 1879, £48,000,000, and in 1888, £67,000,000; average income per head of population £16 in 1879, and £20 in 1888. The number of income taxpayers has therefore increased 22 per cent., and the total amount of their income 40 per cent. in Saxony during the ten years ending with 1888. In Saxony, 40 per cent. of the population pay income tax. Everyone there with an annual income of £15 is subject to income tax. In Prussia all incomes under £45 are exempt for taxation. Prussia, in 1890, showed thirteen persons having an estimated income of over £50,000 each, and Saxony only one. The exhibits of the savings banks also show a general augmentation of the wealth of the people, and since 1875, the number of accounts open and the sums deposited have doubled.

THE FORESTS OF BRITISH INDIA.

The forest lands of India belong chiefly to the State, except in parts of Lower Bengal. It is stated

in a report recently issued by the India-office that the efforts of the Forest Department are directed to selecting the best and most remunerative forest areas as reserves, to conserving them and securing reproduction of timber and firewood, and to working the produce of the reserves to the best advantage. Outside the reserves there are in some provinces very large forest or waste areas which are accessible to the people and can be reclaimed for cultivation when need arrives. The reserves, however, will always be retained as State forests, to be conserved and worked according to the best principles of scientific forestry, for the use of the neighbouring populations and the advantage of the public treasury. The Forest Department is manned by European officers, who have been trained at forest schools in Germany and France, or at Cooper's Hill College, and also by Indian and other officials trained in the forests or at the Indian Forest School established at Dehra in the North-West Provinces. Timber, firewood, and other forest produce in the reserves are worked out in rotation, or on other scientific principles, so as to prevent exhaustion of the supply. Natural reproduction is safeguarded by the exclusion of the yearly fires which used to devastate most Indian forests; and artificial reproduction is effected by systematic plantations. Forest revenue is raised by selling or giving permits for timber, for firewood, for charcoal, for bamboos, for grazing, or for older minor forest produce, with due regard to the claims and comfort of neighbouring rural populations. The extensive State forests and wastes outside the reserves are worked so as to produce revenue and to meet local demands, with such rough and inexpensive conservancy as may be practicable. Private forests, wherever demand for timber exists, are being worked with little regard to reproduction; and this circumstance makes the careful conservancy of public forest property all the more important. Forest conservation began in some parts of India more than forty years ago, but systematic conservancy under regular forest laws began under the forest administration of Dr. (now Sir Dietrich) Brandis, about the year 1862. There are now in British India about 64,000 square miles of reserved forests, of which 6,000 square miles were reserved during the year 1890-91; there is also an area of about 50,000 or 60,000 square miles of other State forest, parts of which may hereafter be reserved, but Madras and Burma are the only provinces in which further extensive reservations are likely to be made. Most of these reserves have been properly demarcated, and in all of them full investigation and settlement of private rights have been completed, or are in progress. Systematic fire protection was, in 1890-91, carried out over varying proportions of the reserved forests in the several provinces, with the result that fire was absolutely excluded from more than 95 per cent. of the protected area in all provinces except Bombay and Burma. Regular plantations of the best timber-bearing trees cover 95,000 acres, of which 4,200 acres were added during the year 1890-91. The total forest revenue of British India was Rx. 1,448,000 in 1890-91, against an expenditure of Rx. 784,000, leaving a surplus of Rx. 664,000 as compared with a surplus of Rx. 706,000 in the preceding year. The chief surplus provinces were Burma and Bombay. The reduction of the surplus was due to a decrease of revenue in Burma, and to a small increase in the cost of the forest staff. About one half of the gross revenue was yielded by timber operations, and the remainder by firewood, charcoal, grazing dues, bamboos, rubber, and other minor forest produce. A large quantity of teak timber and cutch (a substance extracted from the heartwood of the acacia catechu, and used for tanning, dyeing, and for preserving nets) is sent from Burma to Europe; and small, but increasing, quantities of rubber, of forest gums and fibres, of bamboo canes, and of wild silk, are exported from India. The great bulk, however, of the yield of the forests is consumed, and most of the forest revenue is paid, by the people of India.

MANUFACTURE OF SILK FROM WOOD PULP.

The United States Consul at St. Etienne says that the reported failure of the silk crop in France, Italy, and Syria has again directed the attention of some of the most important manufacturers of St. Etienne to the process invented by Count Chardonner for the manufacture of silk from wood pulp by a method similar in principle to that employed for converting wood into paper. A few years ago the new invention was brought out, and the rights to its exclusive use were sold to companies in Germany, France, and England. Large works were built at Besançon, and preparations for manufacturing silk from wood were projected and made on a somewhat extravagant scale. Some remarkable specimens of silk made by this process were shown, but it was found that the fabric so manufactured could not be woven successfully in large pieces, and that it was of so highly inflammable a nature as to be a source of great danger. The experiments were then dropped, and nothing was heard of the matter until a few months ago, when a company was organised at St. Etienne to develop the process of Count Chardonner and make it a thoroughly practical one. This company is quietly at work now, and is making a large number of experiments which, Consul Loomis says he has been informed by those in a position to know, are likely to lead to some important and satisfactory results. It is affirmed that in a short time the company will be able to offer to the trade a substitute for silk which will possess all the essential qualities of silk, and which can be sold for less than half the cost of the genuine article.

FIBRE AND FRUIT CULTIVATION IN THE BAHAMAS.

In a recent report by Sir Ambrose Shea, Governor of the Bahamas, it is stated that fibre cultivation makes very satisfactory progress in the colony, and there are now about 8,000 acres planted out, and it is expected that at least 6,000 acres will be added during the present year. A larger addition would be made, but that the supply of plants of the requisite growth is as yet limited. It is now ascertained that it is not advisable to transplant from the nurseries until they are at least one year old, and have attained a length of twelve or fifteen inches. It is anticipated that the export from early plantings will amount to about a hundred and fifty or two hundred tons in 1892, and this quantity will probably increase, but an estimate shows that it will not reach beyond 14,000 to 15,000 tons up to the year 1900. It is now ascertained that with plants of fair growth four years is the longest time for the maturing of the plant, and it then yields an annual crop, without further care for twelve or fourteen years. The available supply of fibre at present is not more than is required for the needs of the colony, which would be hampered by outside demand, and the progress of the colony be consequently retarded. It would be difficult, it is said, to assign a limit to the future advance of the colony from the growth of this remarkable industry. Though the land provisionally assigned to fibre cultivation (100,000 acres) will in time yield 50,000 tons, there appears to be no reason why even this great result should bar the extension of the area of production, if the markets admit of its profitable disposal. It is generally thought that, from the excellence of the fibre, it will find its way into other fields for its use besides rope-making; and recent experiments prove that it takes a dye readily, indicating its adaptability to certain fabrics, and to some extension of demand on this account. There is the further ground for the probably strong place for Bahamas' hemp in the future, that it can be produced more cheaply than any known fibre of equal value, and it may be inferred that it will hold its own at least against the influence of any probable competition with which it may have to contend. As regards fruit-growing, the Bahamas offer very great facilities. Pineapples are at present the principal crop, but the particular description of land required for their culture is very limited. Of late years the growth has been much improved by the use of fertilisers, with a considerable increase of quantity. The crop yields large profits. At twopence each, an acre of pineapples returns £40 to £45; and although precarious from its perishable nature, while such results are possible, it is likely that pineapple-growing will continue to be an attractive pursuit. In oranges a good business, it is said, might be done, if the accounts of Florida enterprise in this fruit are a fair criterion. At present the oranges of the Bahamas are roughly handled, being generally shipped in bulk in the holds of vessels, often without compartments. The fruit is held to be equal to any in the world, and as at present it receives little or no attention, the result of careful cultivation could not fail to be remunerative. The facilities for production are fully equal to those in Florida, and the Bahamas are entirely free from all risk of frost, which so often blights the Florida crop. The success of the industry in the colony would be partial, however, until the proper system of packing were adopted to ensure delivery at market in good condition; with this point secured, and the advantages of steam communication, which is fast becoming available, orange growing would be a profitable industry. Tomatoes are grown to a moderate extent, but the production, it is said, might be largely increased. Sir A. Shea says that it is to be regretted that, of the many young Englishmen who embarked in orange growing in Florida with chequered results, and of those also who sought their fortunes in South America, some, at least, had not found their way to the Bahamas, where energy and thrift, applied to the varied resources, can hardly fail to reward well-directed efforts, and where personal rights and property are under the protection of British laws and administration.

General Notes.

CHICAGO EXHIBITION.—Mme. Carnot has accepted the presidency of the committee, whose business it will be to organise the French exhibits in the section of women's work at the Chicago Exhibition, and the members of which are:—Mme. G. Berger, Mme. Bertault, Mme. Bagelot, Mme. Brouardel, Mme. Miolan Carvalho, Comtesse H. de Chaiseul, Mlle. d'Eichthal, the Générale Février, Comtesse Foucher de Careil, Comtesse de Grandval, Comtesse Greffulhe, Mme. Coralie Cohen, Mme. Kœchlin-Schwartz, Mme. Madeleine Lemaire, Mlle. Laiziblen, Mme. Lourdelet, Mme. H. Mallett, Comtesse de Montsaulnin, and the Marquise de Moustier. Their meetings are to be held at the Palace of the Elysée.—*The Queen*.

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

FRIDAY, AUGUST 5, 1892.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Chicago Exhibition, 1893.

FINE ARTS COMMITTEE.

A meeting of the Fine Arts Committee was held on Tuesday, 2nd inst. Present: Sir Frederick Leighton, Bart., P.R.A., in the chair; J. Macvicar Anderson, Pres. R.I.B.A., Wyke Bayliss, Pres. R.S. Brit. Artists, Philip H. Calderon, R.A., H. Stacey Marks, R.A., Deputy-President R.S.P.W.C., Walter William Ouless, R.A., Marcus Stone, R.A., with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission, and J. W. Beck, Secretary to the Committee.

REPORT ON A VISIT TO CHICAGO, JUNE, 1892, BY THE SECRETARY, [redacted] HENRY [redacted]

In accordance with the instructions of the Commission, I left England on the 15th June, and arrived in Chicago on the 25th June, having made a stay of two days in New York.

I crossed in the *City of Paris*, of the Inman Line, and I think I ought to express my appreciation of the accommodation which that company afforded me, on both the outward and the homeward voyage. Both voyages were illustrations of the luxurious and comfortable manner in which it is now possible to cross the Atlantic in the ships of this and of the other great steamship lines.

I have also to express my obligation to the New York Central Railroad authorities, who favoured me with a free pass over their line. on going to and returning from Chicago. When Mr. Dredge and I visited America last autumn, we were the subjects of equal kindness and attention on the part of the Pennsylvania Railroad, and that company kindly offered similar liberal treatment to myself on the present occasion. I was, however, anxious to get the fullest information as to the various routes from New York to Chicago, and therefore preferred to avail myself of the kindness of the New York Central. On either line the journey is now made in 25 hours, by two express trains daily in either direction, leaving New York and Chicago respectively in the afternoon and evening. Both trains are fitted in the most luxurious manner; and it is no exaggeration to say that the journey is made with no greater discomfort than that of remaining in a well-furnished hotel. It, indeed, involves less tedium than an ordinary journey of 300 or 400 miles in this country.

Visitors who desire to see Philadelphia and Washington will prefer the Pennsylvania line; those who care to break their journey at Niagara will take the New York Central. Both lines pass through fine scenery: the Pennsylvania crosses the Alleghanies, while the New York Central runs by the side of the Hudson, and through the Mohawk Valley. With regard to the comfort of the journey, there is little to choose between them. The New York Central has the advantage—to English notions—that, if privacy is desired, separate small rooms can be obtained, fitted [redacted] for the accommodation of one or two [redacted]engers.

On arriving at Chicago, I was met by Colonel Grover, R.E., who had been there since the 6th May last, in charge of the arrangements for the erection of the building for the British Section. I should like to take this opportunity of expressing my appreciation of that gentleman's services. I shall refer to the progress which has been made in the construction of the building later on; but I may say here that Colonel Grover has been untiring in his devotion to the interests of the Commission. Not only has he taken great pains in carrying out their wishes with regard to the building, but he has also rendered valuable services in regard to many other details of the Exhibition work.

I cannot let this opportunity pass without reference to the kindly and generous manner in which the demands of the Commission have on all occasions been met. In every building in which we are exhibiting Great Britain has been assigned a prominent and advantageous

* As presented to the Royal Commission, this report contained detailed information on various matters of a more or less confidential character, and on matters of organisation not of special interest. The passages relating to such subjects have been omitted.

position. Had the Commission been allowed to select for itself the various allotments it could hardly have selected better positions than those voluntarily assigned to it. Where all the officials have shown themselves so helpful, it seems almost invidious to particularise. Yet I cannot abstain from expressing my sense of the value of the services rendered by Colonel Davis and Mr. Baker, the heads of the two important organisations by which the Exhibition is controlled, by Mr. Burnham, the Chief of Construction, and by Mr. Fearn, the Chief of the Foreign Sections. All the official correspondence with the Commission has been conducted by the last-named gentleman, and it has throughout been of the most friendly and pleasant character.

Condition of the Buildings.

One of my first duties was to visit Jackson-park, and see the progress which had been made in the buildings there. Very great advance has been made since my visit in September last, quite sufficient I should say to justify the belief that the buildings will be completed, though not ready for the reception of exhibits, by the date of the inauguration ceremonies in October.

The buildings are in various stages of completion. The most backward is the great Manufactures Building. This, I was informed, has been delayed by the necessary materials not being all ready for delivery by the appointed date, but even it is very far advanc[illegible] Seventeen of the twenty-three great roof trus[illegible] of the main structure were in position before I left Chicago, and the remainder will doubtless be set up by the end of this month.

On the other hand, some of the buildings are practically completed. The Mines Building is quite finished, except as to the interior decoration. This, it appears to me, is the building best suited of any for exhibition purposes; for, its roof being constructed on the cantilever principle, there is no necessity for the supporting pillars which, in many of the other buildings, occupy a large amount of space. This is especially the case in the Agricultural Building, the galleries in which are very extensive, and in consequence, the ground floor space is very much obstructed by numerous supporting pillars. The general effect of the whole will, I think, be a good deal impaired in consequence. On the other hand, the large area of the gallery gives a great deal of exhibition space, and as access to the gallery is obtained direct by the Elevated Railway which runs through the grounds, the galleries are more accessible to, and will doubtless be more visited by, the public than is usually the case at Exhibitions. This building is in an advanced stage of completion, being roofed in, and the exterior nearly completed. The same remarks as to gallery apply, to a large extent, to the Transportation Building. This also is roofed in, but is not quite so far advanced as the Agricultural Building. The gallery in this appears to me to be the best exhibiting space in the building, having regard to the fact that it also is accessible direct from the Elevated Railway. The large annexe to the building has not yet been commenced. This, however, will consist practically of shedding only, so that it can be run up in a very short time.

The Machinery and Electricity Buildings were not so far advanced. The scaffolding being still up, it was not possible to form so good an idea of what their internal appearance will be when completed.

The Horticultural Building is completed outside, and partly finished within; indeed, some of the conservatories are already heated for the reception of plants.

The shell of the Forestry Building has been finished for some time. It is now used as a workshop for the moulders, who are making ornamental statuary in "staff," or fibrous plaster, for the exterior of the buildings.

The Fisheries Building is externally com-[illegible] and the construction of the aquaria and [illegible] with. This is one of the most original and attractive buildings on the grounds. Its style is generally Spanish Romanesque; the arches, capitals, and shafts of the columns are decorated with figures of marine animals and plants, treated somewhat in the same way as the animals which compose the terra-cotta decoration of the Natural History Museum in London.

The walls of the Fine Art Building are built, but the roof is not completed; still, I was able to form a good idea of what the structure will be like when completed. It seems to be admirably suited for its purpose; the rooms will be spacious, and promise to be well lighted, and the arrangements are such that they are all easily accessible from one another, and from the Central Hall. I should think that large crowds could pass through the building without inconvenience. Had the Exhibition Executive realised, in the first instance, how large would be the contributions to this department from foreign countries,

they would probably have designed a larger building at the outset. The two annexes have not yet been commenced.

The Women's Building is practically finished; it is of rather plainer and more unpretentious character than most of the other buildings. It consists of a central hall with rooms opening out of it on the ground floor, and rooms above on the second storey opening into the gallery surrounding the hall. A portion of the roof, I understand, is to be laid out as a garden and restaurant. From it one of the finest views of the park will be obtained.

It is now quite possible to judge what the general aspect of the park will be when the buildings are complete, and there seems no reason to doubt that the high anticipation formed from the design, as to the effect of the magnificent buildings surrounding the lagoons which have been formed in the centre of the park, will be fully realised, and that the general effect will compare not unfavourably with that of the Paris Exhibition of 1889. Having regard to the size and extent of the buildings, it can hardly be expected that they will be more splendid and imposing, as being on a larger scale, than even that presented by the Champ de Mars.

The principal means of access to Jackson-park is, at present, the Illinois Central Railroad, which runs trains at short intervals from its station in the centre of the city to Jackson-park, the journey occupying about 30 minutes. In addition to this there is a service of c[illegible] cars which is being improved and developed in view of the Exhibition, and there has also been recently constructed an Elevated Railroad. This is now at work for some distance from the centre of the city to the suburbs, and is being carried on to Jackson-park. Access can also be had by the lake steamers. A new and special service of these is being organised for next year. These steamers will form a very pleasant but less speedy means of reaching the park than the railroads. At present the tracks of the Illinois Central Railway run by the side of the park on the level, but works have been designed and are on the point of commencement, for raising the track along the whole length of Jackson-park. This is a very necessary undertaking, as otherwise the crowds arriving by car or vehicle from the city would have to cross, on the level, the whole of the lines of this important railroad, one of the greatest leading into the city.

In consideration of the size of the park it has been thought well to make special arrangements for the conveyance of visitors from point to point within it. For this purpose a special service of launches (steam or electric) is being organised for the lagoons and canals which form so special a feature of the grounds, and there will also be an "intra-mural" elevated railway extending from one end to the other of the Park, and arranged so as to convey visitors to the principal points of interest.

Pricing Exhibits.

On Monday morning I called on Colonel Davis, Mr. Baker, and other principal officers of the Exposition, and took this the earliest opportunity of bringing before Colonel Davis the question of pricing the exhibits. Mr. Medill, the proprietor of the *Chicago Tribune* newspaper, came in with a telegram on the same subject from Mr. McCormick, as I was on my way to Colonel Davis's offices, and we saw that gentleman together. The question once raised was promptly settled in the simplest and most satisfactory manner. Colonel Davis at once frankly stated that the writing of the letter which he had signed to the Acting-Secretary of State had been a mistake. He said that his views on the subject had never varied from what he had verbally stated last September, and had since confirmed in the letter written by Mr. Fearn, on the 11th December last, I asked him to refer to my letter to Mr. Fearn, of the 28th November; this he did, and he stated that it distinctly and accurately [illegible] conditions under which exhibitors would be allowed to mark their goods. He further stated that he would at once write to the Secretary of State, explaining that his previous communication had been in error and withdrawing it. This he afterwards did, and a copy of his communication will be found in Appendix No. I. I also took this opportunity of bringing a copy of the resolution passed by the Commission on the 14th June last with regard to Mr. McCormick, and suggested that it might at once be transmitted to the newspapers for publication.

Colonial Allotments.

A matter to which I devoted a good deal of attention was that of the Colonial allotments.

The Hon. J. J. Grinlinton, the Commissioner for Ceylon, had been in Chicago for some little time before I went there, and remained during my stay, returning to England with me. By his able and energetic advocacy of the claims of the colony, he had succeeded

in obtaining very advantageous allotments for it.

The principal object of the Ceylon Commission is to bring Ceylon tea prominently before the American public, and the arrangements which Mr. Grinlinton was successful in making may be expected to effect the object in view.

At my request Mr. Grinlinton has kindly furnished me with a report on his proceedings, which I have added as an appendix to this report. (Appendix No. II.)

Mr. Saunders, the Commissioner for Canada, was in Chicago when I arrived, and was good enough to extend his stay there a few days, that we might have the benefit of discussing matters.

Mr. Berliner, the resident Commissioner for the Cape, visited Chicago during my stay, and Mr. Hutchinson, a Member of the New South Wales Commission, was also there for a short time. I was thus able to discuss with all these gentlemen the requirements of their respective colonies.

In the Manufactures Building I was able to secure a small further addition to the space assigned to Great Britain and the Colonies.

In the Agricultural Building I felt justified in giving up as much as it seemed possible to spare of the space to the Colonies, on condition of a little addition to the total being made, and of a space in the grounds being allotted for the exhibits of bakery machinery in action.

In the Mines Building, also, the total space was extended by about 2,000 feet.

In all cases, the British and Colonial allotments are contiguous, this arrangement being desired quite as strongly by the Colonial representatives as by the Royal Commission.

The total space allotted to the Colonies is over 110,000 square feet; and there is still a portion yet undisposed of in the Manufactures Building. The total space available for exhibits from the United Kingdom is over 220,000 square feet. To this must be added a considerable amount of space in the grounds for the various outside exhibits, perhaps 14,000 or 16,000 more. When all these are added together, it will be found that the total area is not far short of the largest ever occupied by this country at any foreign exhibition—viz., 360,000 in Paris, 1878.

India.

Much disappointment was felt at the absence of an Indian Section, and even now, though it is too late for space in the buildings to be allotted, I believe the Executive would willingly provide a location in the grounds for an Indian building, could one be provided.

At the request of the London Committee of the India Tea Planters' Association, I secured for that body the promise of a space in the grounds on which to erect a building for the exhibition and sale of Indian tea, and I hope that arrangements may be satisfactorily made for the representation of, at all events, this one article of Indian commerce.

Offices of the Royal Commission.

For the erection of the British Pavilion a contract has been entered into with the George A. Fuller Company, of Chicago. This company (who are architects and engineers as well as builders) are perhaps the leading firm in the city, and have constructed many of the enormous buildings for which Chicago is remarkable. They were recommended to the Commission by Mr. Burnham, the Chief of Construction, who has throughout shown much interest in the work of the British Section, and whose kind advice has in this special matter been of the greatest assistance to the Commission.

Under the care of Colonel Grover, R.E., whose services for this special duty the Commission wore fortunate in being able to secure, all the preliminary arrangements for the construction of the building have been made, and the building itself commenced. The foundations are in and the walls carried above the [illegible] of the ground. More than this it was not possible to do until the terra-cotta, as designed by Colonel Edis, the honorary architect, had been prepared. This is now being made in Chicago, and as soon as it is ready the construction of the building will be continued, so that at all events the shell of the house may be completed before the winter.

The example of the Royal Commission in erecting a special building for their offices has been followed by the Commissions for Germany, France, and Canada. The British building, however, is the only one which has been commenced.

The design of the house has been greatly admired, and it may be hoped that its solid and genuine character may not be without a good effect among a mass of buildings which, however imposing in character, are of course of a purely temporary character.

There seems every reason to believe that the building may be sold for a price which will cover at all events a proportion of the cost. Colonel Edis has designed it with this end in

view, and in putting it up the necessity for its ultimate removal will be borne in mind.

Electric Lighting.

I made inquiries as to the arrangements for electric lighting, and ascertained that a small amount both of arc and incandescent lighting is being retained for foreign exhibitors, and that if any English company desired to take this up on the terms which have already been published, they could do so. The main bulk of the electric lighting has been arranged for on a commercial basis with American firms. They have not yet got all the power required for running dynamos, and would be glad if English exhibitors could send one or two 500 horse-power engines for the purpose. These engines would be placed among the lower plant, and the space allotted for the purpose adjacent to the Machinery Hall.

Such engines would have to be delivered free on the cars at Jackson-park. Foundations would be provided and the engines erected by the Executive. The cost of running would also be provided, including wages of engineer, who might, if preferred, be appointed by the exhibitors, but would be under the orders of the Executive. Engines on the same bed plate as dynamo would be quite acceptable. At the close of the Exhibition the engines would be dismantled and placed on the cars.

Special arrangements are to be made for the lighting of the Electricity Building. In this each foreign section can, if it chooses, light up its own space.

It is proposed to allow exhibitors to furnish all the lighting plant as exhibits. Steam would be provided free, but no payment would be made. Exhibitors who require current or light, and who do not provide generators, would be charged a low rate. Mr. Hornsby, the Chief of the Electricity Department, could not say what the rate would be, but it would be about cost price. The motors and generators would be placed among the power plant above referred to. Exhibitors would be expected to lay their own cables in the conduits, do their own wiring, provide lamps, &c. The generators, cables, &c., might be supplied by different exhibitors.

Exhibitors generating current would be allowed to use as much light as they pleased for themselves. In addition to the light thus supplied, the building will be lighted by arc lamps. For this light there is to be no charge.

Motive Power.

Mr. Robinson, the Superintendent of Machinery, would be glad if an English exhibitor would supply an engine of about 300 or 400 horse-power, to drive one of the lines of shafting in the British and German Court. The Germans propose to erect an engine, and this would drive the second line common to both Courts. The conditions on which this engine would be accepted would be the same as those for engines for running dynamos.

Music.

I had several interviews with Mr. William L. Tomlins, the Choral Director, and with Mr. Wilson, the Secretary of this Department.

The Department is inviting the principal composers in foreign countries to visit Chicago for the purpose of conducting each of them a work of his own. In this country they have invited Dr. Mackenzie, and, but for his severe illness, would have invited Sir Arthur Sullivan.

Before going to Chicago, I had had some communication with Dr. Mackenzie, who is likely to accept the invitation. It is proposed that a formal invitation should be addressed to him through the Royal Commission. The Committee have in contemplation the engagement of military bands, but no money has yet been voted for the purpose, and the arrangements are as yet incomplete. They have had some communication direct with Lieutenant Dan Godfrey, and, through myself, with Mr. Edward Holland, of the Scots Guard Band. I gave them all the information in my power about the English military bands, and promised that the Royal Commission would do anything in their power to further their views. They are also anxious to obtain the services of a good British choir. It is not proposed to pay this choir, but it is suggested they might cover their expenses by giving concerts in Chicago and elewhere.

Some German and Scandinavian choirs are coming over, arrangements having already been made by societies of those countries in America to bring them over and keep them while in America.

Juries.

There is no fresh information on this head. The proposed regulation for Juries are contained in the Report of the Committee of Awards to the National Commission issued some time ago. The acceptance of this report has been delayed, pending a settlement as to

he appropriation by Congress. As soon as this question is settled, the Committee will issue their final regulations. They propose a fee of $1,000 for each foreign Juror. The number of the Jurors have not yet been decided. It is probable that exhibitors will not be appointed Jurors in their own class, but that they will not be prevented from acting on other classes.

Empty Cases.

The regulations for the storage of empty cases have undergone modification, or, rather, are in process of modification; for the latest statement on the subject, which will appear in the forthcoming pamphlet on Transportation—a proof of which was shown me by Mr. Jaycox, the Traffic Manager—is merely to the effect that suitable arrangements will be made for the care of exhibitors' empty cases.

Catalogue.

The arrangements for the Catalogues to be published by the Executive, and the sectional catalogues to be issued by Foreign Commissions, are not finally decided upon. In the official Catalogue, there will be no advertisements. It is proposed to allow every exhibitor three lines free of charge in the body of the work; every additional line, up to seven lines, will be charged for at a price to be hereafter decided. These charges will be made alike to United States and foreign exhibitors. It is not settled what arrangements will be made for collecting the amounts charged.

With regard to the Catalogues of the Foreign Sections, no regulations have yet been laid down.

Women's Work.

I am sorry that I was absolutely unable to obtain any fresh information with regard to the arrangements for the Women's Section. The general character of these arrangements does not appear to have been decided upon; the actual amount of space to be allotted to the different departments has not yet been allotted; nor has the amount of space available to foreign countries been decided. It is the wish of the Committee that they should receive application for space in the Foreign Sections. Since my return, I learn that a formal application for space has been made by the Secretary of the Ladies' Committee.

Fisheries.

I had a long conversation with Mr. Collins, Chief of the Fisheries Department, who is very anxious that Great Britain should be properly represented in his department. At present we have no exhibitors, except a few makers of fishing tackle. He had been in correspondence with some boat builders and others in England, a list of whom he furnished me with, and he thought it might be possible to secure models of fishing vessels and other fishing gear which had been prepared for and exhibited at the South Kensington Fisheries Exhibition. Besides models of trawlers, &c., he would be glad to have a few examples of actual gear, trawls, nets, seines, traps, &c., also whaling gear, and the products of the whale, seal, and walrus fisheries. He expected to have a good collection of specimens from the Cape, and was anxious to know what other British colonies would contribute. I undertook to apply to the India-office to know whether the collection of Indian fishes formed by the late Dr. Day could be lent, or any fresh collection formed.

Forestry.

A space of 1,700 square feet is being reserved in the Forestry Building for India, in the hope that a specimen collection of Indian forestry products may be sent. Since my return I learn that a small collection may be expected.

Charitable Exhibits.

Mr. Rosenau, the Superintendent of the Bureau of Charities, had been in communication with Mr. Loch, of the Charity Organisation Society, about exhibits of charitable and philanthropic societies. Mr. Loch has had some communication with myself. Mr. Rosenau showed me a draft of an explanatory circular, which he said would be ready in about a fortnight, stating what this department desired. Reports, literature, charts, plans, statistics, &c., are amongst the things they seek. Full details will be given in the circular. I said I would suggest to the Royal Commission the appointment of a small committee, of whom Mr. Loch might be one.

Leather Exhibit.

I had one or two meetings with Mr. Macfarlane, the Chairman of the Leather Trades' Committee of the Exhibition, and also with Mr. Oakley, a member of that Committee. The Committee have raised a sum of money by contributions from representatives of the eather trade, with which they propose to erect

a separate building on a site to the north of the Dairy Building, and facing the lake. In this they propose to make as complete an exhibition as possible of leather, and applications of leather, both from the United States and from foreign countries. They are anxious for British exhibits; and I undertook, on the part of the Commission, to try and organise a small collective exhibit of British leather. Mr. Macfarlane promised to send me full details as soon as they were printed.

Live Stock.

Mr. Buchanan, the Chief of the Agricultural Department, gave me a little information about the arrangements for live stock. He said he could easily make arrangements for keeping stock of one sort while another was being exhibited, so that an exhibitor showing both cattle and sheep might have his cattle looked after while his sheep were being exhibited, and *vice versâ*.

Mr. Buchanan told me that the Agricultural Department at Washington had lately prohibited the importation of sheep from certain parts of Great Britain, on account of foot and mouth disease. He had very little information about it, but mentioned the matter in case we thought it desirable to protest.

He promised he would send on by next mail a complete memorandum of the alterations in the arrangements for exhibiting live stock. In the meantime he gave me the following dates:—

Horses and Cattle show together......	Aug. 21 to Sept. 21.
Sheep and Swine show together	Sept. 25 to Oct. 14.
Fat Stock	Oct. 16 to Oct. 28.
Poultry	Oct. 16 to Oct. 28.
Dogs	June 12 to June 18.

Transportation.

A new circular is in preparation, giving certain modifications in the rates for freight by rail to Chicago, and further information as to the methods of conveying goods to the Exhibition. I was shown a proof of this by Mr. Jaycox, the Traffic Manager, and hope soon to receive copies of the completed pamphlet.

Dedicatory Ceremony.

I took the opportunity of ascertaining the views of Mr. Baker on the subject of the Dedication Ceremonies. He stated very distinctly that he would much rather have people over there during the Exhibition than at the Dedication, if they were only able to visit Chicago once, though of course he would be glad for some representatives of the Commission to go out in October. There will of course be nothing to see at that time, as the buildings, although no doubt in a very forward state of completion, will not be entirely completed. There will be three days' festivities, and of course the ceremonies will be made of as imposing character as possible.

I discussed the question with other officials, and I gathered that it was the general opinion that members of the Commission who had it in view to pay a visit to Chicago would do well to make that visit during the continuance of the Exhibition, and not on the occasion of the Dedicatory Ceremonies, though they were gratified to learn that there would probably be a few members of the Commission present besides her Majesty's Minister at Washington.

APPENDIX I.

Pricing of Exhibits.—Letter of Director-General Davis.

"Chicago, Ill.,
"June 29th.

"*To the Honorable the Secretary of State, Washington, D.C.*

"Sir,—The publication in England of the letter which I had the honour to address the department under date of March 11th, 1892, in reply to the inquiries of Consul Augier, of Feb. 15th, 1892, in behalf of certain woollen manufactures of Rheims, has led to the inquiry from British manufacturers whether my letter was intended to revoke the permission previously given to foreign manufacturers to placard their exhibits with the prices at which they will be sold in bond.

"The paragraph in my letter of March 11, 1892, which refuses permission to the manufacturers of Rheims to placard their prices as requested in the letter of Consul Augier was a mistake, and I desire, therefore, to have that letter revoked by authority of the department, and the following statement sent out to Consular officers as the correct ruling in the case:—

"'Foreign exhibitors in the World's Columbian Exposition will be permitted to state upon placards attached to their exhibits the price at which said products will be sold at the place of manufacture, and also the prices in bond and out of bond, or exclusive and inclusive of the Customs duties in Chicago.'

"Asking that the same publicity be given by the

department to this correction as was given to my letter of March 11, I have the honour to be, very respectfully yours,

"GEORGE R. DAVIS,
"Director-General."

APPENDIX II.

REPORT OF THE HON. J. J. GRINLINTON, COMMISSIONER FOR CEYLON.

"Cannon-street Hotel, City, London,
"22nd July, 1892.

"*To Sir Henry Wood, Secretary to the Royal Commission, World's Columbian Exposition.*

"SIR,—1. In compliance with your request, I have pleasure in stating generally the steps taken by me at Chicago to obtain sites at the Great Exposition for the Ceylon Court and Tea Kiosks.

"2. At an interview which I had the honour of having with you, prior to my departure for America on the 4th May last, you were so good as to express approval of the steps taken by the Ceylon Government and the Planters' Association to send a Commissioner to Chicago on a preliminary visit, to see for himself what arrangements could best be made, and what sites could be obtained at the Exposition grounds for a Court and Tea Kiosks. You also mentioned that you thought, in the interests of the colony, it would be well if I acted independently, and on my own responsibility.

"3. Acting on your advice, which concurred with my own judgment, I proceeded to America, and immediately on my arrival at Chicago, on the 18th May, I waited on the Director-General of the Exposition (the Honourable Colonel Davis), also on the Honourable Walker Fearn (Chief of the Department of Foreign Affairs), and on the Directors and heads of departments, and explained the object of my visit, the nature of the exhibits which might be expected from Ceylon, and the paramount object which the Government and planters of Ceylon had in view in taking part in the great Exposition, namely, the desire to place Ceylon teas (which were so very favourably known in other countries) in the American market.

"4. I was met by all the authorities of the Exposition in a most friendly spirit, and succeeded in obtaining their co-operation, with authority to construct a principal Court, and Tea Kiosk (made of the woods grown in Ceylon), on a favoured plot of ground facing Lake Michigan, close to the British Head Quarters Building, and between the sites granted to France and Austria. I also obtained permission to occupy favoured sites in which Ceylon will have miniature Courts in the Agricultural Building, the Manufactures Building, and in the Woman's Building. The extent of each allotment has already been communicated to you. In all four Courts there will be suitable exhibits, and tea will be distributed gratuitously or by sale in packages, and also infused and served in the cup to such visitors as may desire it, under conditions which have been satisfactorily arranged with the authorities.

"5. Having obtained the objects sought in visiting Chicago, I made the necessary arrangements to go on with the foundation of the Ceylon Main Court, and other matters in connection with the Exhibition, including the selection and lease of suitable accommodation for the staff which will be sent from Ceylon early in 1893.

"I left Chicago on the 9th inst., and arrived at Liverpool in the s.s. *City of New York* on the 20th inst., and hope to reach Ceylon on the 30th August—returning again to Chicago with staff and exhibits in February, 1893.

"6. I cannot conclude this report without recording the obligations which Ceylon is under to the Director-General of the Exposition, Colonel Davis; to Mrs. Potter-Palmer, the accomplished President of the Board of Lady Managers; to the President, Mr. Baker; and the Vice-President, Mr. Higinbotham; to the Honourable Walker Fearn, the Chief of the Foreign Department; to Mr. Burnham, Chief of Construction; to Mr. Buchanan, Chief of the Agricultural Department; and to Mr. Allison, Chief of the Manufactures Department; also to the heads of the various other departments, who were most obliging in rendering their aid in every way they could.

"7. To yourself allow me to offer my best thanks for the information and assistance afforded to the colony I represent at the Exposition, and for the courtesy and consideration extended to me personally.

"The thorough and hearty co-operation of yourself and Colonel Grover, R.E., were such as to be of great help, not alone to Ceylon, but to every country which has the honour of acknowledging British rule and the influence of the Royal Commission.

"I have the honour to be, Sir,
"Your most obedient Servant,

"J. J. GRINLINTON,
"Special Commissioner for Ceylon to the
"World's Columbian Exposition."

Miscellaneous.

THE TIMBER TRADE OF BOSNIA AND THE HERZEGOVINA.

The superficial area of Bosnia and the Herzegovina is 51,155 square kilomètres (12,641,133 acres), of which more than half is reckoned as forest. A great part, however, of this so-called forest is mere brushwood, while other parts have been so devastated by neglect and reckless cutting as to be almost valueless at present as regards their timber. Her Majesty's Consul-General at Serajevo says that in the more mountainous parts of Bosnia and Herzegovina, far removed from the waterways, there are still extensive forests of very fine timber, in some parts even untouched yet by the axe. In the north, oak, fir, and beech predominates; in the south and west, beech and various coniferæ. It was only about the year 1830 that the timber trade in Bosnia commenced, and it was confined to the production of oak staves, as requiring neither costly establishments nor carriage roads. These Bosnian staves soon acquired a certain reputation on foreign markets, and were known in France as *Merrains de Bosnie*. In England all staves coming from Austrian ports were known as Bosnian staves. The oak found in the hilly part of Bosnia is the *Quercus robur*. Only, as rare exceptions, in certain marshy places, are found specimens of *Quercus pedunculata*, which is of quicker and larger growth than *Quercus robur*. The *Quercus robur* of Bosnia is of particularly slow growth. A tree 250 years old does not measure more than 17¾ inches in diameter; and trees rarely attain a diameter of 25 inches, and those that do show already signs of decay. The wood is softer, and less durable than the oakwood of Slavonia; but, on the other hand, it is more elastic, and easier to work. In Slavonia, it is not uncommon to find trees up to 50 inches; but, on the right bank of the Save, none such are—now, at least—to be found. The Bosnian staves, consequently, run somewhat smaller than the Slavonian staves. The latter average about 4·9 inches in breadth, and the former only 4·7 inches. A forest law existed in Bosnia under the Turkish Government, but it was never put in force, nor were there any forest *employés*. When the Austrians occupied the country in 1878, measures were immediately taken for the preservation of the forests from further devastation. By the new Austrian law all the forests in Bosnia and the Herzegovina were proclaimed to be State property, unless the ownership of private persons or of Vakuf (Mussulman Church) could be clearly authenticated. A Special Commission was appointed to carry out this work, which is yet far from completed. The forests are classed under the four following heads: — State property, Vakuf (Mussulman Church property), private property with unrestricted rights, and private property charged with certain communal rights. The peasants are allowed, as before the Austrian occupation, to cut wood and make charcoal for their use in the State forests in the vicinity of their abodes without payment, and have also the right of pasturage therein for their cattle. On all wood cut and charcoal made for sale they have to pay a tax. For some years after the Austrian occupation the timber to be cut was sold by public auction, previous notice of the intended sales being given in the newspapers, but this system has been abandoned of late in favour of private sales. Sales up to the value of 50 florins can be concluded by the district authorities (*Besirksämter*), and up to 600 florins by the Departmental authorities (*Kreisämter*), but above that amount only by the Central Administration at Serajevo. The cost of the staves to the cutters of course depends very much upon the position of the forest where they are cut, and the distance they have to be carried either to the railway or to a navigable river. For instance, a thousand staves cut near the Save would probably not cost more than 50 florins (£2) delivered at the frontier, whereas the same number from the interior of Bosnia would cost as much as 250 florins (£10). It is reckoned that in Bosnia three quarters of the price of a stave goes in freight, and in Slavonia less than half. A good workman in Slavonia cuts about 10,000 staves in a season, and is paid 20 florins to 22 florins per 1,000. In Bosnia, owing to the mountainous nature of the country, the severity of the weather, and the rugged growth of the trees, a workman cannot cut more than 6,000 to 7,000, and is paid 36 florins to 37 florins per 1,000. Cutting only takes place during the winter months, and ceases at the end of April. The staves are mostly sold either at the nearest station of the Bosna Bahn (Brod-Serajevo line), or at Sissek, which is the principal market for this article, whence they are sent by rail to Fiume or Trieste for shipment. There has been an enormous increase during the last five years in the number of staves exported from Bosnia. For example, in 1886, the number exported was 2,500,000; in 1888, 8,000,000; in 1889, 14,000,000: and in 1890, 26,000,000. Consul-General Freeman believes that these figures are rather below than above the mark, and has heard that the 1890 export amounted to as much as 30,000,000 staves. Taking the average price per thousand delivered at the frontier at £9, the value of the trade has risen from £22,500 in 1886 to £234,000 in 1890. About 90 per cent. of the staves produced are what are known in the trade as French staves, and the remaining 10 per cent. as German staves, these latter being larger, thicker, and more coarsely cut for the manufacture of large barrels. France takes nearly three-quarters of the number exported. The next best customer is Italy, and then Algeria, England, Portugal, and Spain, in the order given. Fiume is rapidly supplanting Trieste as a port of shipment for staves. The trade in Bosnian staves is said to be

passing through a very critical period. The production is ever increasing, but not the demand, and the capital engaged is said to bear at present but a low interest. There is also the fear that the oak forests of Thessaly and Asia Minor, which are as yet untouched, may prove dangerous rivals to those of Bosnia and Slavonia.

THE MINERAL PRODUCTS OF VENEZUELA.

A recent bulletin of the Bureau of the American Republics states that gold has been found in all the States and territories of Venezuela; but the deposits of greatest extent and value are those discovered in the Yuruary region, where the El Callao mine is situated. There are also out-croppings in all the mountainous lands between the Yaracuy river and the cities of San Filipe, Nirgua, and Barcelona. Near Carupano are some valuable mines, that have yielded seven ounces of gold per ton, besides others in the same locality that bare rich deposits of silver, copper, and lead. Valuable mines of copper at Aroa, in the hills of San Filipe, 70 miles west of Puerto Cabello, have long been worked, and the ore, which is a red copper of excellent quality, and preferred to the Swedish or Chilean ores, is exported to Europe. There are also undeveloped mines of this metal in Coro, Carabobo, Barquismeto, and Merida. There are many indications of red hematite and magnetic iron ores in the littoral Cordilleras, in the mountains round Coro, Barinas, Barcelona, and Cumana, and many parts of the Parima mountains; but the most valuable deposit is near the Imataca river, a confluent of the lower Orinoco, where an inexhaustible quantity of magnetic ore, assaying 80 per cent. of pure metal, lies exposed to view, and accessible to deep water. A lead mine, undeveloped, lying near Tocuyo, has yielded some valuable specimens. Tin ores are also found near Barquisimeto. Asphaltum exists in great abundance near the Pedernales river, an estuary of the Orinoco, opening into the Gulf of Paria, where petroleum wells have been sunk with good results, and a company has been organised in Caracas to work the property. The machinery is on the spot and in process of erection. Inexhaustible mines of mineral pitch also exist near Maracaibo, Merida, and Coro. Petroleum wells are abundant in Cumana and Trujillo. On the island of Pedernales, which is formed by the two delta streams, the Cucirina and the Pedernales, its northern shore being that of the Gulf of Paria, is found a vast supply of asphaltum. The land is low, intersected by small streams, and containing many ponds of salt and brackish water. In such ponds on the northern shore is found the asphaltum known as Pedernales asphalt. This differs in the main from that found at La Brea in Trinidad, in being generally more liquid, purer and freer from earthy matter, and in containing a greater per-centage of oils. Like the deposit at Trinidad, this is found in a series of springs in conjunction with water, and, as at Trinidad, it forms a thick flooring of pitch in places, and to an appreciable depth. The Pedernales asphalt is remarkably pure, and when refined, presents a hard, lustrous, vitreous fracture, and in appearance is identical with the Egyptian refined, known in trade as "Epuré." As found it is a thick, black, viscous mass, without odour and strongly adherent. The process of refining consists in merely boiling it, thus depriving it of a large proportion of the higher volatiles and all contained moisture. Refining may be carried on to any degree, even to the extent of complete reorganisation. The deposits at Pedernales may be said to be the same, geographically considered, as that of La Brea, notwithstanding that the Trinidad contains a quantity of earthy matter, well nigh inseparable, although mechanically mixed. These earths are mainly very finely divided clays, held in suspension by the viscous asphaltum. The presence of these impurities adds largely to the weight, and, while proving little detriment to the many uses of the material, debars it from many other purposes. The Pedernales deposit can be used for any purposes known in the arts, and is as desirable for varnishes and chemical compounds as it is useful in increasing the elasticity of the asphalt, which contain too small a per-centage of volatiles. The Pedernales asphalt can be refined to order, thus exactly fulfilling desired conditions imposed by users. Extensive coal deposits are found about 12 miles from Barcelona, and the area, only partially explored, discloses about 100 overtoppings of coal strata of regular formations, varying from four inches to seven feet in thickness. These strata are situated between layers of sandstone and schist, in the general direction of east to west, with an inclination of 45° to the south. This is also the general direction of the valleys where these deposits lie, through which run streams to the Neviri river. Large quantities of coal crop out above the level of the streams, and can be mined from horizontal tunnels and loaded upon cars without expensive pumping and lifting machinery. The quality of the product is such as is termed steam coal, and is easily ignited, producing much combustible gas, with a small proportion of argillaceous cinder, and a very small quantity of sulphur. In mining and transportation, it loses about 25 per cent., most of which can be recovered and worked into patent fuel. A rich salt mine, upon the peninsula of Araya, discovered in 1499, is still worked, from which the Government of Venezuela has derived a revenue, since 1873, of nearly $3,000,000. It consists of an inexhaustible deposit of almost pure salt, which is mined at very small labour and cost. In Lagunillas, near Merida, is a lake, the bottom of which is covered with *uras*, or sesqui carbonate of soda. Unworked mines of sulphur exist in Cumana, Barcelona, and Coro. Mines of jet and porcelain earth are found near Cumana and Caracas. Granite is abundant in the Silla Mountain, near

Caracas; and slate, marble, granite, gypsum, and lime exist in great quantities in the Coast Range and Parima Mountains. Thermal and mineral waters are found in many parts of the country. The hot springs of Las Trincheras, on the railway between Puerto Cabello and Valencia, are specially noted, their waters maintaining a temperature of 206° Fahrenheit. With the exception of the Urjino Springs in Japan, having a temperature of 212°, these are reputed to be the hottest springs in the world. Some remarkable springs are those of Coro, in La Quiva, near the road to Pedregal.

COAL DEPOSITS IN VICTORIA.

The "Victorian Year Book" for 1890 91, referring to the mining operations for coal recently carried on in the colony of Victoria, states that many attempts have been made to mine for coal, but the seams hitherto worked have been too thin to yield a profit. The reported discovery of thicker seams, however, and of large deposits of brown coal, chiefly in South Gippsland, led to the appointment, in July, 1889, of a Royal Commission, which was instructed to "inquire into and report as to the best means of developing the coal-mining industry of Victoria. This Commission has brought up a progress report, in which several seams of true coal, situated in different localities, are referred to, varying in thickness from 2 feet to 4 feet 6 inches; and in the annual report of the Secretary of Mines for 1890, it is stated that, by means of five diamond drills which were employed during the year, a seam of 3 feet 2 inches was discovered at Boolarra, and six seams at Korumbarra, varying from 2 feet 6 inches to 4 feet 11 inches in thickness of good coal. Early in 1891 the continuance of the Yambunna seam, of nearly 5 feet in thickness, and the discovery of a seam, said to be over that thickness, at Korumbarra, were reported, and coal mining at the two places named was being actively carried on. The deposits of brown coal, or lignite, in Victoria, are practically unlimited, and are thought to represent the largest supply of fossil fuel known in the world. The Coal Commissioners, in their first progress report, mentioned one mine, in which the thickness of the deposits ranged from 60 to 200 feet. They say that the brown coal differs materially from the black, both in appearance and character. It belongs to the tertiary formation, and represents only a partial degree of mineralisation. It is comparatively light, burns freely when dry, gives off a strong heat without smoke, and leaves a very small per-centage of ash. Its principal drawback arises from the quantity of moisture it contains, and the fact that the gas extracted from it is of low luminosity. A second progress report gives the result of a series of practical experiments with a view of ascertaining the value of brown coal for manufacturing, domestic, and other economic purposes. In regard to its illuminating power as compared with good coal gas, a ton of which should yield from 10,000 to 11,000 cubic feet of gas, of from 15 to 17 candle-power, and a residue of 12 cwts. of good marketable coke, it was found that, although from 6,447 to 15,083 cubic feet of gas was obtained per ton from the brown coal, the highest degree of luminosity was only 9·3 candle-power; and in some cases it was *nil.* For steaming purposes it required from 2·16 to 2·42 tons to do as much work as one ton of small Newcastle coal, whilst it required more stoking, and its comparative value for heating purposes was estimated at 8s. 4d. per ton as compared with 15s. 7d. for Newcastle slack. These experiments were made on the crude coal as it was taken from the mine, and it sometimes contained from 36 to 56 per cent. of water, the average being about 40 per cent. In the form of briquettes, however, there was evidence leading to the belief that it would be well adapted for domestic use; and with a view of placing the brown coal industry on a sound and permanent footing, the Commissioners recommended that a qualified person should be despatched to Europe for the purpose of acquainting himself with, and reporting upon, the methods adopted in Germany, and other countries in Europe, for raising and sending the coal to market, manufacturing the raw material into briquettes, and the application of the fuel to the industrial arts, to locomotive, domestic, and economic purposes. In accordance with this recommendation, Mr. Y. Cosmo Newberg, C.M.G., was despatched to Europe by the Government with instructions to inquire into and report upon the subject. At the present time the coal-producing colonies of Australasia are practically New South Wales, New Zealand, and Queensland, while small quantities have been found in Tasmania and Victoria. In these over 4,000,000 tons of coal were raised in 1890, but three-fourths of this quantity come from New South Wales.

PRODUCTION OF MACEDONIAN TOBACCO.

M. de Lacretelle, French Consul at Salonica, in a report to his Government, says that Macedonian tobaccos are universally known and appreciated; from time immemorial their excellent qualities have enjoyed a high reputation in foreign countries. It would be difficult to specify the period at which the cultivation of tobacco was first engaged in, but the industry dates from a very remote period, and for some years it has experienced a great development. Europe, Asia, Africa, and America purchase largely from the markets of Cavalla and Salonica, and to supply all the demands it has been necessary to increase the production to a very considerable extent. Since the establishment of the Ottoman tobacco monopoly, the cultivation of this article is subjected to stringent regulations, and although it is not limited, it is not free. The grower is obliged to make a declaration of the extent under cultivation; his plantations are inspected, and his product is

scrupulously verified. He is not bound to sell his product to the *Régie*, while the latter is obliged to purchase all that is offered to it. The trade in, and export of, tobacco in the leaf are authorised, but they are subject to control. The tobaccos are divided into two categories—the *bachi-baghli* and the *basma*. The former is distinguished by very pronounced stalks at the base of the leaves. When this tobacco is made up into bundles, the extremity of the bundle is formed by these stalks, which are tied with thread—hence the name *bachi-baghli*, or "heads tied." The *basma*, on the other hand, which have a very small stalk, are put up in bundles without being tied. The *basma* tobacco is considered to be very superior, and realises higher prices than *bachi-baghli*. In the production of the weed, Macedonia may be divided into two districts—the district of Cavalla, which is comprised between the Rivers Nestus and Strymon, and the region formed by the sandyak of Salonica, by the sandyak of Uskub, in the vilayet of Kossoos, and by the districts of Monastir and Serfidjé. In the latter region, which has a very extensive area, a large number of places are devoted to the cultivation of tobacco. The best known are those of Karaferia, Langhaza, Kilkich, Yenidjé, and Doïran in the vilayet of Salonica, of Perlipé and Florina in the sandyak of Monastir, of Elassona, Caïlar, and Nasselitza in the sandyak of Serfidjé. From the district of Salonica about 694 tons of tobacco were exported, and 350 tons retained for home consumption in 1890. The Cavalla district, from the point of view of the tobacco production, is a far more important one—the annual product varies between five and six thousand tons. The chief producing districts of the Cavalla region are—Sérès, Nevrokop, Djoumaia Pétrés, Drama, Sara-Chaban, and Cavalla. The district of Névrokop only produces *bachi-baghli* and the Sari-Chaban district *basma*, all the other districts yield both varieties. The finest descriptions of the former variety are those of Persotzan, Carlikova, and Coubalista, while those *basma* tobaccos, which are considered of the finest quality, are known by the names of Carchi-Yaka, Kirs, and Mahalés Kirs. The Persotzans, Mahalés Kirs, and Kirs are grown in the district of Drama. The Persotzan tobacco is moderately strong, of a clear colour, and a sweet taste; the Névrokop tobaccos are strong, the leaf is well developed, colour pronounced, and are frequently used for blending. Djoumaia Petris is an ordinary tobacco of rather bitter taste. The Mahalé Kir are very fine tobaccos with a small leaf, a good aroma and colour. Kir is a fine tobacco with a leaf more developed than the Mahalé Kir, and is considered of excellent quality for smoking. The Pravista is a light tobacco with a large leaf, it is largely exported to England and Austria. Cavalla does not only export the product of the districts comprised within the region of Cavalla, properly so called, but also part of the product of the districts of Xanthi, Yenidje, and Gumurgina, which extends from the Nestus as far as the Rhodope mountains, and comprises the plain situated between these mountains and the sea. Xanthi produces very excellent tobacco, particularly the description known as *yaka*, which enjoys a high reputation. For these tobaccos the principal consumers are Austria-Hungary, Egypt, Russia, and Germany. The methods of cultivation in Salonica, Uskub, and Serfidjé, and those practised in Cavalla and Xanthi are very different. In the former districts little care is devoted to it, whereas in the latter the greater attention is bestowed upon it. The ground is sown at the end of February, and in May, when the plant has attained a certain height, the first leaves are gathered—these are small and are found at the base of the stalk, and are known as *dipe*. These are in many cases considered as worthless. Towards the end of June the good leaves are gathered, these are called *cirindjiana*, and a few days later further leaves, known as *ikindjianas*, are harvested. At the beginning of August leaves higher up the stalk are plucked, the first being known as *outzoundjon-ana*, the second *outz-alk*, and finally the *outz* are arrived at, which are considered as the finest leaves of all. The harvest finishes in September. The yield is a particularly good one if the season is a rainy one after sowing, at the end of July and at the beginning of August. If the rains fall too heavily after the 15th August, the leaves develop quickly, but the quality suffers, and the colour of the tobacco is turned black. The leaves are picked as they mature, and considerable experience is necessary to know the exact period of maturity; if they are gathered too late the leaf becomes burnt up by the sun, and if too soon it remains green and turns out a bad quality. The leaves, when gathered, are strung together and hung up and exposed to the sun for about a week, until they are dry, when they are placed in warehouses, out of the rain. To commence the operation of separating the perfect leaves from the defective, it is necessary to wait for the first winds from the south, which give flexibility to the leaf. This operation lasts many months, as it is frequently interrupted by cold, which has the effect of rendering the tobacco dry and too friable. To avoid this danger, and to give more elasticity to the leaf, the growers frequently hang them in damp underground cellars. Merchants commence to make their purchases in January, and at the end of February all the tobaccos have been placed on the market. Exportation cannot take place before August, as tobacco is subject to fermentation in June and July, and it would be dangerous to manipulate the leaves. The culture of tobacco is very remunerative to the grower in Macedonia when a drought does not spoil a part of his harvest, and the prices now realised are far in excess of those ruling twenty or twenty-five years ago.

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

Journal of the Society of Arts.

MEETING OF THE ROYAL COMMISSION.

A meeting of the Royal Commission was held on Wednesday, 10th inst. Present: The Attorney-General, Q.C., M.P., in the chair; Sir Frederick Abel, K.C.B., D.C.L., D.Sc., F.R.S., Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D., Sir Edward Braddon, K.C.M.G., Major-Gen. Sir Owen Tudor Burne, K.C.S.I., C.I.E., Michael Carteighe, R. Brudenell Carter, F.R.C.S., B. Francis Cobb, Prof. James Dewar, M.A., F.R.S., General Donnelly, C.B., Sir Henry Doulton, James Dredge, Walter H. Harris, C. M. Kennedy, C.B., John Biddulph Martin, John Fletcher Moulton, Q.C., F.R.S., John O'Connor, William Henry Preece, F.R.S., Sir Albert K. Rollit, M.P., Lord Thurlow, F.R.S., with Sir Henry Trueman Wood, M.A., Secretary.

EXECUTIVE COMMITTEE.

A meeting of the Executive Committee was held on Wednesday, 10th inst. Present: Sir Frederick Abel, K.C.B., F.R.S., in the chair; Sir George Birdwood, K.C.I.E., C.S.I., R. Brudenell Carter, F.R.C.S., Francis Cobb, Sir Henry Doulton, James Dredge, John B. Martin, W. H. Preece, F.R.S., with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

HORTICULTURAL DEPARTMENT.

The following letter from Mr. J. M. Samuels, Chief of the Horticultural Department, to Mr. McCormick, has been communicated to the Royal Commission:—

July 22nd, 1892.

Hon. R. S. McCormick, Official Representative, &c., &c., &c.

Dear Sir,—I am sorry to learn that information prevails among the British horticulturists that they will be "boycotted" by American dealers, should they attempt to make an exhibit at the Columbian Exposition. I have had similar information before from France and Germany, but from investigation I learn that this sentiment exists only among a few importers in New York.

I was informed by the German seedsmen that letters had been received by them from Americans—whose names they withheld for business reasons—to the effect that they would be "boycotted" if they made an exhibit at Chicago. I immediately wrote to a number of seedsmen throughout the country, and received replies from many of them couched in words of indignation that they should be accused of such actions.

At a meeting recently of the American Seed Trade Association, they passed very strong resolutions denouncing such action, and cordially invited seedsmen and horticulturists from all parts of the world to make as grand a display as possible.

Mr. Maurice L. de Vilmorin, of Paris, who at first hesitated to take part in the Exposition—for the reasons now first given in your letter—has recently been very active, and a few days ago submitted a proposition, by authority of the Horticultural Committee of France, to decorate all the grounds surrounding the Women's and Horticultural Buildings of the Exposition. This will require an expenditure of something like $100,000, to transport men and material.

Of all the countries in the world, the American horticulturists have been looking forward to the finest display being made by Great Britain, and I trust they will not be disappointed.

Very respectfully,

(Signed) J. M. Samuels,
Chief of the Horticultural Department, Chicago.

VISIT TO THE RUINS OF SUKKHOTHAI AND SAWANKHALÔK, SIAM.

By Ernest Satow, C.M.G.*

The result of my inquiries had been that Phichhai was the most convenient starting-

* Mr. Ernest Satow read a paper on "The Laos States, Upper Siam," before the Foreign and Colonial Section, on January 12 last, and the following account of his visit to the ruins of Sukkhothai and Sawankhalôk, in December, 1885, is extracted from his journal, which he kindly left for publication when he returned to Siam.

point for a visit to the ancient cities of Sukkhothai and Sawankhalôk, and at Phitsanulôk I had arranged with an officer whom I met there to procure eight elephants for the journey. On these were loaded a portion of our stores, and baggage sufficient for a week's use, the rest being sent on by the boat up to Utaradit on the same river. It took a couple of hours to pack the elephants, as the drivers are very careful not to overload their animals, and it is no easy matter to divide a large number of packages so that each beast gets a weight proportioned to his strength. Two elephants were specially reserved for Archer and myself, but I preferred starting on foot. The path lay for some distance through the jungle, which was still wet with dew, and then came out to a monastery (Wät Mô) standing amongst shady groves of fruit trees on the left bank of the river. But it was already getting too hot to walk, so we rejoined the main track to wait for the elephants, which soon made their appearance. As a rule, it may be said, that in Siam an elephant carrying what is considered a full load makes from two to two and a half miles an hour. It (he or she) appears to move each leg separately, and the rocking motion thus communicated to the howdah is extremely fatiguing. When I got off my elephant the first day, after about three hours' ride, my loins ached as if they had been well beaten, and even after becoming more accustomed to being shaken in this way, I never cared to ride on the elephant, except when fatigued by walking or by riding on horseback at a footpace. The howdah is a sort of covered tray supported by wooden frame-work in the shape of a V turned upside down, the covering being so constructed that the rider can see but little of the country through which he is passing. Underneath the tray there is sufficient space to hold a few light boxes of no small size. You spread a small mattress in the howdah, and wedge yourself in as best you can with pillows and cushions. Perhaps the least uncomfortable way of travelling on an elephant is to sit in front of the howdah with your feet on his neck, and your knees consequently somewhat pushed up towards your face. The mahout rides on the front part of the animal's neck with his legs, which he constantly agitates, dangling behind the huge ears, and it is the pressure on the latter that indicates to the elephant which way to go. A certain number of words are used to direct him to kneel down, lean his body on one side to avoid a projecting branch, or tear off with his trunk a bough that threatens to strike the howdah. When the elephant is disobedient the mahout strikes him on the head with a sharp spike fixed into a wooden handle, and not seldom makes the blood flow. When the elephant is displeased or frightened he either "trumpets" or omits a harsh snort like the sudden letting-off of steam. As he goes along he is constantly engaged in eating grass, leaves of trees, young twigs and branches, no matter whether thorny or not. Even bamboos covered with prickles are not despised. When he gets in at night he is fed with cocoanut leaves or sliced banana stems. After using his trunk all day in procuring his food, or smelling the ground in order to find where to place his next footsteps, he curls up its end and rests it on the earth. Sometimes you will see him with his trunk hanging over one of his tusks, in an attitude of deep contemplation. He is very fond of squirting dust over his back and under his belly, and of washing himself when he gets a chance. In passing a stream he never loses the opportunity of getting a drink of water, which he sucks up his nostrils as far as the root of his trunk, and then inserting the end into his mouth, he discharges the contents without even as much noise as well-bred people make in eating their soup. He has a tail like a bellpull, fringed at the end with hairs, and a small yellow eye indicative of cunning. The ear is like the door of a small cupboard, constantly flapping backwards and forwards. Looked at from behind he resembles a short-necked old gentleman with a scanty pigtail, whose gouty legs, encased in baggy shapeless trousers, move with the greatest possible deliberation.

From the spot where I mounted my elephant, which I had to do by climbing up a ruined tree, the mountains were visible far away to the east over a wide plain. Soon we had to leave the open track, and plunge into deep thickets, where the mahouts cut their way with knives through the overhanging branches and matted creepers. These knives, which are made in the country, resemble a midshipman's hanger, and may be used for a variety of purposes, including self-defence. However, you will oftener find a man employing his weapon to divide an areca-nut or to peel a section of sugar-cane. About noon we came to the river, and descended the steep bank with perfect ease and safety. I suppose an elephant scarcely ever stumbles in the course of a long life. In going down hill, where he

cannot walk, he folds his hind legs under him and slides slowly down, using his forelegs to regulate the rate of descent, while to ascend he adopts the opposite plan of climbing up on his front knees and pushing his huge bulk upwards with his hind legs. We crossed the river at Tha Maphueng, the grown-up elephants wading, while a baby elephant who came along with his mother swam with the tip of his trunk just above water. This little creature, who stood about three feet and a-half, was inclined to be gamesome, and offered to charge anyone who went near him, but his weight made it advisable not to try a fall. He seemed to be a pet with the other elephants, almost as much as with his own mother. I did not see any signs of the vindictive character so often ascribed to these animals, and certainly if they were capable of resentment, they would exhibit it towards their mahouts. But on the contrary, they stand in the greatest awe of their drivers, and their personal courage is in the inverse proportion of their size. They displayed the greatest alarm at the sight of a horse, and Archer's little black dog was a terror to them. That old story of the tailor who was deluged with dirty water by an elephant in return for a prick with a needle comes from Siam. It is told by one of the Frenchmen who visited Siam about 200 years ago, but I have never been able to find any confirmation of it, though I have inquired of several Siamese. Probably it was invented by one of the resident European merchants, and swallowed with the same avidity as the modern globe trotter gulps down the fables he picks up at dinner-parties on his way round the world. The best account of the elephant I have ever seen is to be found in Sir Emerson Tennent's "Ceylon." At first I was rather kept in awe by all I had heard about the animal, but afterwards, becoming more familiar, used to offer them bananas, which they took from my hand with the greatest gentleness, using, however, the mouth instead of the trunk, which they do not like to have touched. You never saw anything more weak-looking than an elephant's mouth, with its long pointed under lip, like that of an old man who has lost all his teeth. An hour after crossing the river we passed a few houses, and arrived at a *sala*, or large wooden shed, by the side of a pond, where I was glad to get down on to my feet again. Hearing that the next stage would be a long one, I resolved to remain here for the night. The *sala* was charmingly situated, in the middle of a forest, and surrounded by deep grassy glades, with groups of cocoanut and sugar-palms dotted about here and there. There were no mosquitoes, though the stagnant pond looked well contrived for breeding them in myriads.

At two o'clock in the afternoon of December 17th, 1885, we reached the town of Sukkothai, built on both banks of the Më-yom, which is here deep, though narrow.

The vice-governor of the province, who was at Phitsanulôk when I passed through on the 11th December, had been sent across country to make preparations for my reception, and I found he had got quarters ready for me in a large hall belonging to the principal temple of the town. It was what the Siamese call *Kanburien*, a sort of church, provided with three magnificently - carved and gilded pulpits. Round the upper part of the wall ran a painted frieze, representing scenes from the anterior lives of Buddha, but unfortunately there was no one in the place who could explain them. Such knowledge is extremely rare among the Siamese, perhaps rarer than that of the lives of the Catholic saints in England amongst Protestants. The roof was supported by rows of lofty circular pillars of rosewood, nearly two feet in diameter. It is, perhaps, necessary to observe that this timber takes its name not from the tree whence it is obtained, but from its red colour (*couleur rouge*). Along the side of the hall ran a raised platform, on which we deposited our baggage and had our bedding spread out. The rest of the afternoon was spent in arranging for a visit to the ruins of the ancient town of Sachanalai, in collecting information about the resources of the province, and in exploring the temple grounds. There was nothing particularly remarkable about the principal building, containing the image of Buddha (*wihan*), but in a shed close by, I found a collection of old bronze figures which had been brought from the ruins, and were now undergoing restoration with the aid of pieces of wood, paint, and the replacement of lost arms and legs by modern castings. Archer occupied himself in superintending a tracing of a native map of the province which the vice - governor had lent us, and in getting from that worthy various items of information which have appeared in the official report of our journey. Not being able to speak Siamese, I left all such matters entirely in his hands.

At six o'clock on the morning of December 18th, the thermometer stood at 69°, showing

that we must have descended considerably since we left Phichhai. At half-past seven we started on elephants from the opposite bank of the river for Sachanalai. The road lay at first along the muddy bank of a creek, which it then crossed, and we did not see it again till shortly before we got to the ruins. We passed three small hamlets, and traversed a good deal of rice-land, of which only about one-half had been sown this year, owing to the deficient rainfall, for, as you know, the cultivation of rice is almost entirely dependent on an abundant supply of water. Every now and hen our followers climbed a fence to rob a sugar-cane field of its luscious produce, which they peeled and devoured greedily, not however without giving the elephants a share. At a quarter-past ten we passed a tall *phra-chedi* of comparatively modern date, rising among some trees to our left, and entering a wood reached, in half-an-hour more, a *wat* standing on the edge of a lotus pond. Here on an island in the middle of the water is a half-ruined *phra-chedi* of stuccoed brick. Halting for a few moments at the *sala*, we proceeded on our elephants for 40 minutes more to the principal ruins, which the Vice-Governor had caused to be cleared in great part of the overgrowth of bushes that would otherwise have rendered them inaccessible.

The first object that attracted my attention was a massive square structure standing on a platform rising by steps from the general level of the soil, and on examining it closer I found the platform to be constructed entirely of blocks of stone, covered with a coating of very hard chunam. This is a very important fact. All of the buildings in Bangkok are of brick, and that material seems to have been universally employed in modern times, so that the mere fact of stone having been used is by itself an indication of great antiquity. The Sachanalai stone is laterite, which, when dug out of the ground is so soft that it can easily be cut, but it becomes extremely hard after exposure to the air.*

In the centre of the eastern side was a narrow and lofty opening, the sides of which approached each other towards the top, forming a truncated acute angle, and across which were laid slabs of what looked like green slate. The outer dimensions were 53 feet 4 inches on every side, the height being apparently the same, and the base was nearly 80 feet square. At the top of the wall were remains of an elegantly mounted cornice. All signs of roof had disappeared, but I incline to the belief that it must have been pyramidal. There were traces of a porch having existed over the doorway.

From the measurements I took, the walls appear to be over 8 feet thick at the sides; and the inside of the building is, therefore, only about 37 feet across. At about three-quarters of their height from the floor, the walls begin to incline inwards, and, if continued upwards in the same curve, would terminate in a sharp, many-sided point. The concealed passage starts from one side of the entrance, and, winding upwards, seems to pass out on to the top of the wall behind the image. On the south side it opens into the interior by a doorway 5 feet high and 2 feet wide. Unluckily, we had no candles, and therefore could not explore the passage. These passages have since been examined by Pere Schmitt, who found them to be covered with sculpture incised on blocks of stone. The walls are of large red bricks, covered with stucco.

East of this building there had been a *wihan*, the outer walls composed of low, cylindrical, laterite pillars, covered with stucco, the space between having been filled up with brick, while two rows of similar columns mark off the aisles. Fragments of a coarse pottery, having a pale, stone-coloured glaze, and picked out with designs of light brown, were lying scattered about. They take the form of Buddhist angels, lions, and small pagodas, their precise employment being uncertain, but they were probably intended for decorative purposes. There are also numerous small Buddhist images, of a fine-grained green stone, resembling slate, the largest fragment being a head about eight inches high.

From this place I returned with Archer to the *sala* for lunch, and afterwards visited the ruins of a temple mentioned in history as the Wât Na Phra-that. It consists of a much larger group of buildings than the first one. The principal edifice is a *wihan* 136 feet in length, and about 40 feet wide. The roof and walls have long ago disappeared, but many of the four rows of laterite pillars which ran down each side of the building, giving it three aisles with a broad nave between, are still erect. These pillars diminish in height and size from the nave outward, the highest being about 25 feet, and are built up with thick circular slabs of stone, covered over with chunam. The

* Being of a deep red colour, it is a very effective material, and in Rangoon, where it abounds, it has been recently utilised for public buildings.

outer walls were of brick. At the eastern end we found a block of green stone half sunk in the ground bearing an imperfect inscription. Beyond this is a small shrine raised high above the level of the floor, the roof of which had been supported on four pillars. The image of Buddha which this shrine once protected from the weather is still in position, though much dilapidated.

At the other end of the building is a large *phra pang*, or group of nine pagodas, having a common base built partly of brick and partly of laterite. Much of this is in ruins, but considerable remains of chunam reliefs show that it was once a very fine work of art. One of these reliefs appears to represent the death of Buddha. Behind it are eight pillars belonging to the *bôt*, a building where the consecration of the priests takes place. On either side of this again rose a sort of cella with thick walls, containing an image of Buddha 40 feet high, nick-named Sao sip-ha pi, "the girl of fifteen years," the tradition being that they are the exclusive handiwork of a damsel of that age. Close by there is a stone called the Khóm dâm dîn, or "Cambodian who dived into the ground." It is connected with the legend of the freeing of Siam from the yoke of the Cambodians by the celebrated magic-working King Phra Ruang. He had fled hither from Cambodia, and was pursued by a Cambodian general, who dived through the earth in search of the fugitive, and came out at this spot in the centre of the temple. On his inquiring where Phra Ruang was to be found, the latter replied "Remain where you are till he comes," and the Cambodian thereupon was transformed into stone. It is said that the present stone is only the remains of a pillar, fragments of which have been carried off from time to time to be used as charms, so that very little of it is now left. According to the Siamese official chronology Phra Ruang reigned about 1250 years ago, so that the temple would be even older, but I fear their dates are not to be trusted.

More remains of buildings were to be seen in the jungle, but it was impossible to trace their outline, owing to the thickness of the brushwood that has been allowed to almost cover them from sight.

We took just three hours to get back to Sukkhothai, arriving there after sunset by the light of the full moon.

About half-past one on December 20 we reached the Ban Wang Mekôn, the seat of government of the province of Sawankhalôk. The court-house (*sala klang*), on the left bank about the middle of the town, had been fitted up for my accommodation by bringing away from the governor's house (he was absent) part of the bamboo and palm-leaf walls and partitions, and supplementing them with curtains. Moreover, there were tables and chairs lent by a rich Chinaman, the local spirit farmer. Mats and carpets had been laid down, the neighbouring ground had been cleared of weeds, and a kitchen and bath-room had been constructed close by. The elephants arrived by land at the same moment that we came in by water, but as the authorities had taken so much trouble to make things comfortable, I renounced my intention of going on that day. In the absence of the governor at the seat of war on the north-east frontier, I was received by the *palat*, or vice-governor, a one-eyed man, who seemed to be crammed with want of knowledge about the resources of his province. Sawankhalôk is famous for the ancient chinaware which was made at the old city in prehistoric times, and specimens are now and then available. I asked the vice-governor if he could help me to purchase some, and later on he brought a bowl of earthenware with a pale-green glaze, which he pressed me to accept as a present. I declined to deprive him of this valuable curiosity, but regretted afterwards the excess of delicacy that had led me to refuse the offer, when I learnt that he had appropriated it from the original owner without payment.

The river is now very shallow, but it is said that at high water boats can go much farther up, namely, to Mu'ang Long, on the frontier of Lakhon and Phrë, where there are rapids which prevent aay further progress. The bank is about thirty feet above the present level of the river. Along the left bank extend the houses of the principal officials, built of wood, each standing in a separate compound full of fruit trees. In this it differs markedly from Sukkhothai, where the houses are built side by side close to the river bank, without the sign of a tree. Here the houses are so surrounded as to be almost invisible from the river. To judge from the mere outward appearance you would fancy yourself in the country of the Laos instead of in Siam.

At a quarter to ten, on December 21st, we passed the village of Tai-chai, extending on both sides of the river. There were a considerable number of trading-boats laid up for the season, and in connection with almost every one there had been built a rough shanty on a raft of teak logs. A good

many Chinese were stopping here, and, of course, they had established the inevitable gaming house, distinguished by its orange paper placards covered with characters in black ink. About a quarter before 11, I caught sight of a lofty *phra-chedi* in a conspicuous position on the high river bank, and passing to the right of a considerable hill, covered as usual with trees to its very summit, we arrived by noon at a wood and bamboo building that had been erected some months since for the accommodation of a Siamese prince. It had been much overgrown with weeds, but these had been cleared away in anticipation of my arrival, and were lying in festering heaps in the hot sun. The bamboos of which the inner rooms were constructed had been gnawed by a disagreeable little insect, and the walls were absolutely covered with a thick deposit of yellow dust. The outer part of the building was a sort of open shed with a raised floor and a verandah running round three sides on a lower level. This was utilised as a dining-room and reception-hall for ourselves, while the mahouts and servants lay about on the verandah, taking a silent part in the conversation.

It was not long before we were visited by some priests from the ruined temple close by, and I took the opportunity of asking whether any specimens of the old pottery were procurable. To my great joy they produced two fragments, one of which would have been worth, according to their estimate, a couple of ticals (tical = 2s. 2d.) if it had been whole. I bought both pieces at that price, and the word was immediately passed round the hamlet to bring more. In the course of the afternoon child after child appeared, each with two or three examples that he had dug out of the ruined kiln, where they had been baked centuries ago. I purchased everything. Not one specimen was perfect, and this is the best proof of their genuineness. China and Japan are the only countries where green celadon is produced now, and it would not be worth any one's while to import from those countries the potters' failures, on the meagre chance of selling them at Sawankhalôk to any collector who might come that way. Their very condition confirms the story that they are found from time to time in the heaps of rubbish surrounding the remains of the kiln. I regret I did not visit the spot, which is said to lie some distance to the north in the jungle beyond the old city walls. Of all the pieces I obtained, only one resembled porcelain. It is a small dumpy jar-shaped bottle, with three figures of Buddhist angels under the white glaze. Another resembled our stoneware, and a few specimens were what is called crackle. But the finest were jars of green pottery, much constricted at the neck.

At old Sawankhalôk there are some thirty-five ruined temples, of which the foundations can still be traced, mostly overgrown with brushwood and hidden in the jungle. But close by the rest-house rises the lofty pagoda we saw as we approached the place in the morning, and another temple called Wât Na-Phra-that. This consists of a *wihan* 32 yards long by 10 in width. The nave was originally supported by ten octagonal pillars of laterite, covered with chunam, while the outer walls were built up of brick-shaped laterite blocks between pillars of the same material. These pillars are about three-quarters of a yard in diameter, and about 20 feet high. The side-walls are pierced with windows. At the west end is a large sitting figure of Buddha, built of stone blocks, plastered with chunam, and piled all about the pedestal are a number of smaller images in bronze, ivory, terra-cotta, and wood, in an advanced stage of rust and decay, and mostly wanting arms, legs, or head. I persuaded the priest who showed us round to sell three of these for a tical each. A Siamese official would probably have taken them away without payment. At the eastern end of this *wât* are the ruins of a lofty *phra-chedi*, built of the same stone as the *wihan*, but so disfigured that its original outlines are no longer visible. The *wihan*, however, is in decent repair, having been, until lately, inhabited by the priests. At the south-east corner, outside the porch, is a cellar with thick walls, containing an erect figure of Buddha, as at Sachanalai, and likewise nicknamed the maiden of fifteen. The whole area is surrounded by a solid wall of laterite blocks, on the top of which is a coping of the same stone.

Beyond this, and almost to the centre of an oblong enclosure rises the well-preserved *pra-chedi* already mentioned, forming part of the monastery Wât Phra-prang. The *phra-chedi* must at least be 80 feet high, perhaps 100. The inhabitants give it about 134 feet, but that is no doubt an exaggeration. At the outer entrance to the central cell, which is approached from either side by a steep flight of steps, are a pair of wooden doors, carved in high relief, representing two angles. The drapery is boldly rendered, and recalls to mind the finest specimens of Buddhist sculpture to be seen

in Japan, which are, as is well known, at least eight centuries old. In modern times all these countries have fallen far below their ancient artistic standard, which seems to have been affected by Greek influences derived from north-western India, or, more exactly speaking, the Punjab. At the end of a narrow passage a massive slab of wood closes the inner entrance to the cell, in which is a sitting figure of Buddha of no particular merit.

Immediately east of the *phra-chedi* is a *wihan*, of which most of the pillars and outer wall are still standing; they are octagonal, as in the other temple. At the west end, with its back to the *phra-chedi*, is a sitting figure of Buddha. We can see how these images came to occupy the important place they do in the Buddhist temples. The *phra-chedi* was supposed to contain relics of the cremated body of Gautama, and in front of it the devotees built a shed or hall to protect them from the weather while saying their prayers. Afterwards they placed a representation of Gautama, generally in the act of preaching, be fore the entrance to the shrine containing his relics, and thus, in course of time, the ignorant populace addressing their prayers to the image came to be idolaters, though their priests, as long as they continued to be educated in their religion, knew well enough that the image was a mere symbol and aid to devotion.

The enclosure is formed by a wall of massive circular stone columns placed close together and surmounted by a heavy coping. Round the inside there once ran a cloister supported on circular pillars, the capitals of which were richly decorated with designs in chunam, and the exterior wall of the *phra-chedi* was similarly surrounded by a cloister. At the east and west ends are gateways, each formed of three massive cylindrical pillars, now half buried in the ground. Indeed, it is worth noting that the level outside is much higher than that of the enclosure, which is no doubt to be ascribed to the gradual deposit of soil by the annual floods.

Outside the enclosure, and still further east, is a square building with a pyramidal roof. Here the people still come to present offerings to the Manes of the prehistoric King Phra Ruang, who reigned here as well as at Sukkhothai. I found it crowded with a mass of trash, such as clay elephants with half-burnt bits of joss-stick inserted in the hole where the head should have been, pieces of dirty rag, &c.

The examination of these buildings in a broiling sun was rather hard work, and we went back to the rest-house for a cup of tea before starting for the outer ruins, which were said to be some distance off. In fact, we found it took three-quarters of an hour to get there. The path lay along the western bank of the river for a long way, and then plunging into the jungle, we reached the ruins of Wât Chan Lom, passing what is said to be the site of the old palace. But of this nothing remained, and no wonder, since until within a few years all Siamese buildings, except temples, were constructed of wood. We found the main portion of the ruins to consist of a stone wall enclosing a ruined *phra-chedi*. This stood on a lofty basement, surrounded by seven life-sized stuccoed elephants on each face, except where there was a staircase giving access to the platform. At each corner stood a still larger elephant. Round the next stage were rows of sitting Buddhas in horseshoe niches, five on a side. The spire was quite plain. The enclosure wall is of cylindrical pillars set close together, with a coping.

One point worth noting is that the stone is never carved, all the sculptural ornaments being produced by the aid of very hard chunam (or cement), which probably would last for ever, but for the ruinous force of the plants, chiefly a species of *Ficus*, which thrust down their roots wherever they get a chance, and thus destroy an uncared-for building in an incredibly short space of time.

Portions of the old city wall are still to be discerned, and in fact they lie for some distance along the river bank. The stream makes a very sharp bend just beyond the Wât Phra-prang, and the angle thus formed was doubtless entirely occupied by the city, a line being drawn across the base of the angle so as to connect the bank at two points. About two miles above the bend, within a short distance of each other, are two sets of rapids, formed by masses of rock lying in the bed of the river. We descended to the upper rapids. Large blocks of laterite, half-buried in the bank, lay close to the path, and it is evident that the stone used in constructing the temples must have been quarried in this vicinity, although the priests and villagers said, in answer to questions, that they did not know where it was to be found. The fall of water at this rapid seemed to be about ten feet, and it makes a considerable roar as it rushes down the narrow channel between the rocks. Above it stretches a long placid reach, curving some-

what to the east, between high grassy banks crowned by high forest trees, while below the river flows away less peacefully to the south-east between two low islets.

Miscellaneous.

THE WORLD'S COLUMBIAN EXPOSITION FOR 1893.*

BY JAMES DREDGE,
Member of the British Royal Commission,
AND
ROBERT S. MCCORMICK,
American Representative in London of the Columbian Exposition.

The great size of Jackson-park, which was assigned by the municipality of Chicago as a site for the World's Columbian Exposition of 1893, enabled Messrs. D. H. Burnham and J. W. Root, the engineers and architects of the Chicago Commission, to prepare a general plan of the exhibition buildings, upon the basis of at least 50 per cent. more covered space than was available at the Paris Exhibition of 1889, while at the same time an ample area was left, which the skill of the landscape gardeners, Messrs. Olmsted and Co., has converted into a noble park that forms a suitable setting for the great range of buildings composing the Exhibition.

Except for the fact that Jackson-park is six or seven miles from the centre of Chicago, it is an ideal site for a great exhibition; for as it skirts the southern shore of Lake Michigan the waters of that inland sea can be turned to full account, not only to supply the lagoons, canals, and basins, on which so much of the beauty of the park may depend, but it will afford a means of permitting a naval exhibition to be held which, in completeness, variety, and interest, will be without a parallel. Everyone by this time must be familiar with the form of the triangular piece of ground on which the Exhibition will be held: it skirts the south-western shore of Lake Michigan, and covers an area nearly twice as large as Hyde-park. There is thus sufficient space to allow of the construction of many miles of public walks, and also for the erection of a series of great buildings—to say nothing of very numerous pavilions — which will be devoted to different branches of art and industry, and which collectively will cover no less than 150 acres, or about twice as much as the covered area of the Paris Exhibition of 1889.

There are no fewer than eleven main buildings, devoted respectively to agriculture, machinery, manufactures, and liberal arts, electricity, mines, and mining, transportation, horticulture, women's industry, the fine arts, fisheries, and the exhibits of the United States Government. Besides these, there is also a great monumental building, reserved for the administration. This latter occupies a dominating position at the end of a vast court, around which are grouped five of the principal structures above referred to, and devoted respectively to agriculture, measuring 500 feet by 800 feet; machinery, 492 feet by 846 feet; manufactures and liberal arts, 787 feet by 1,687 feet; electricity, 345 feet by 700 feet; and mines and mining, 350 feet by 700 feet. The effective areas of these buildings are further increased by very extensive annexes, especially those devoted to agriculture, which include several great pavilions for live stock, forestry, dairy farming, and extensive ranges of sheds for the exhibition of cattle. The principal façades of these five buildings just mentioned form the north and south enclosures to the great central court, at the western end of which is the administration building, while the eastern end is extended into the lake by a pier of large dimensions. In the centre of the court is a basin, which will be enriched by monumental fountains, and which forms a connection between the extensive and ornamental waterways of Jackson-park and Lake Michigan. Each of the principal buildings, so far, at all events, as architectural effects are concerned, has been designed by a different American architect, all of them selected on account of their eminence in the profession. Certain leading conditions have been observed by them, so as to secure harmony in the general effects, both as regards proportions and classic character; in other respects each architect has had an entirely free hand in his designs. The buildings themselves, which are magnificent in dimensions and most elaborate in detail, will thus form exhibits illustrating the development to which the science of architecture has been brought in the United States. As the remaining principal buildings on Jackson-park are more or less independent of one another, greater freedom of design was permitted to the architects, but as in the case of the main group, they are also intended to serve as exhibits contributed by Chicago architects. The transportation building, 250 feet by 960 feet, is simple in its outline, and almost barbaric in the richness of its decoration; the horticultural building, almost as big as our own Crystal Palace, is, like it, a magnificent example of construction in iron and glass. The women's building, 196 feet by 386 feet, is the design of a lady architect, and is severely classic in its outline. The art galleries will undoubtedly be the most beautiful structures that have ever been seen at any exhibition; the leading characteristic of the fisheries building will be its picturesqueness, and the United States Government is erecting a structure remarkable for its elaborate architectural effect and the beauty of its decoration. There is no room to speak of the many pavilions that will be scattered over the ground; they will include contributions from every State of the Union, from every nation exhibiting, as well as those erected by the numerous exhibitors privileged

* Paper read at Edinburgh at the meeting of Section G of the British Association.

to erect buildings for themselves. The most varied and interesting of these will occupy a space of ground projecting from Jackson-park, and which will form, practically, a street of nations a mile long. The work of the Exhibition has now advanced so far that it is within measurable distance of completion, and it will scarcely be doing justice to the Chicago executive to say that in extent, beauty, and completeness, it will as far surpass the Paris Exhibition of 1889 as that exhibition eclipsed all its predecessors.

The administration building, of which the main feature is a dome 120 feet in diameter, rising to a height of 275 feet from the ground, is a beautiful example of boldness in design; in the other buildings, with one exception, there is nothing unusual in the dimensions or the treatment, from an engineer's point of view. The roofs are neither very great in span, nor original in design, the main object having wisely been to cover a vast area in the cheapest and most expeditious manner consistent with a realisation of the best effects for the special purpose for which each building was intended. Considerable interest, however, attaches itself to the foundations of all the main buildings. In constructing these, the system found most useful for the great permanent buildings of the city of Chicago has been adopted for these temporary structures; that is to say, a system of independent platform foundations, each unit of which distributes, independently of all the others, a safe proportion of the load which has to be supported by the thin bed. This is a peculiarity which the local conditions of the ground render advisable.

The exception above referred to, when speaking of the engineering features of the exhibition buildings, is found in the great hall devoted to manufactures and liberal arts: this will have the largest roof that has ever yet been constructed. The building covers an area of over 30 acres, and consists of a central gallery, 387 feet clear span, and no less than 210 feet in height: the length of this vast hall is 1,237 feet, and the great roof is hipped at each end. It is surrounded with a series of galleries, insignificant by contrast both as regards height and span. The trusses forming the great roof are of steel, and resemble, to some extent, especially as regards size, the somewhat smaller and considerably lower arches of the machinery hall of the Paris Exhibition, which, up to the present, has surpassed any other structure of the kind.

It will be remembered with what intesest engineers of every nation watched the erection of that great roof, which was undoubtedly a triumph of the contractor's skill. The erection of the liberal arts building is a work of much greater magnitude, but it is being carried out by simpler means, and with greater facility than the Paris machinery hall.

A travelling stage, wide enough to include two trusses and the whole width of the building, is employed. On this staging are two towers, framed in timber, higher than the roof. The erection of the trusses is carried on from the ground and from the staging to a height of about 100 feet, that is to say, to the level of the main platform of the stage. The upper halves of each pair of trusses are put together upon this platform, and when the lower portions are completed and connected with the longitudinal bracing, the inner members of the upper and lower sections are connected by means of pins, so as to form hinged joints. By means of powerful hoisting apparatus, worked from the floor of the stage, the upper halves are then hoisted to their final position, turning on the hinges. When fully raised, the central joint is made good, the outer members of the upper and lower halves are rigidly connected, the hinges are removed, and the permanent joints are completed by rivetting. In this way, the work is rapidly carried on, and it is expected that the building will be ready for the great inaugural celebration in October next.

*SECONDARY BATTERIES IN USE AT THE CENTRAL TELEGRAPH OFFICE, LONDON, FOR TELEGRAPHIC PURPOSES.**

By W. H. Preece, F.R.S.

In a paper entitled "The Use of Secondary Batteries in Telegraphy," communicated to the British Association at the meeting held at Montreal in 1884, an account of a series of experiments was given which had been carried on during the preceding twelve months to determine the suitability of secondary batteries for telegraphic purposes.

Since that time the use of secondary batteries has been extended, and for the past seven years they have been used to supply current to two large groups of circuits, one group consisting of 110 single needles, and the other of 100 Morse inkers and sounders.

To provide a ready means of replacing the battery in case of failure, the leads from the working and reserve cells, which are placed in the basement, are first led up to the test-board in the instrument room, and there joined to a switch; thence the leads are again led to a test-board in the battery room, where the two groups are split up into sub-groups of ten circuits each. The connections are made in this manner for two reasons: first, for facilitating a change of a faulty battery, and second, to prevent a general stoppage of the whole group in the event of a short circuit at any of the instruments, the resistance of the leads between the instruments and the subdividing connections in the basement being sufficient to prevent more than three ampères being taken from the battery by any one of the instruments, even when a short circuit is on. To prevent any damage to the instruments or risk of fire, fuses are placed in the battery leads at each instrument.

* Paper read before the meeting of Section G, at the British Association.

The circuits on the groups mentioned are all metropolitan, and are all, approximately, of the same resistance, no equalising resistances being therefore necessary. The current in each circuit ranges between seventeen and twenty milliampères.

The E.M.F. for the single needles is twenty volts, ten cells positive and ten cells negative, with earth in the centre. For Morse working the E.M F. is eighteen volts.

In addition to these two groups another set of twenty-two cells has been in use since 1889, supplying current for driving the motors of the Delany multiplex distributors. Each of these motors requires a current of about ·12 ampère, and there are ten of them at present driven from this source. Fuses are placed in the leads to each motor. There is no spare set for this work.

A considerable extension of the accumulator system has recently been made, advantage being taken of the transfer of all the Continental service to the General Post-office building in St. Martin's-le-Grand. This transfer was made on October 17th, 1891, and since that date the whole of the Continental circuits have been operated by currents from secondary cells.

There are fifty-nine of these Continental circuits, and as they are of various lengths, some requiring repeaters in England, whilst others go direct to the Continent, a somewhat different arrangement has been adopted. In addition to these varying conditions it was found impossible to use the same polarity in all countries, the German, Dutch, and Belgian lines taking positive, and the French negative.

It was also necessary to provide an arrangement which would cause the stoppage of the minimum number of lines should a main fuse be burned or a battery fail.

The fifty-nine lines are divided into four groups; but as the force required for these long lines is 100 volts, it is evident that the risks of allowing a dangerously heavy current passing out from the instrument to line should it make earth near the sending station, is increased. To provide against this, resistances of 100 volts are placed in the battery leads at each instrument, so that it is absolutely impossible that more than one ampère can flow even with earth on the line close up to the instrument. Independent three-ampère fuses are also fitted to each instrument to prevent any damage to lines or instruments should the safety resistance be short-circuited.

As it is sometimes necessary to put repeaters in on the English side of the cable on some lines which nominally work direct to the Continent, the resistance blocks on several of the instruments are wound to 1,000 ohms, and fitted with a switch which enables either 100 ohms or 1,000 ohms to be inserted in the battery circuit, and thus the current is kept constant. In addition to the independent three-ampère fuses, main fuses to break at ten ampères are placed on each group of circuits in the accumulator room.

All the coils are kept well charged, and the E.M.F. is not allowed to fall below 1·95 volt per cell. Where spare or reserve sets are provided the charging is carried on at any convenient time, and on those where no spare is in use the charging is done at night, when the minimum disturbance is caused by the slight increase of E.M.F. which is inseparable from simultaneous charging and working.

Accumulators are also used for working the Paris telephone circuits. Their E.M.F. is so constant that they are found to be eminently adapted for the purpose.

THE INDUSTRIES OF MOROCCO.

A meeting of the Geographical Society of Leipzic has recently been held in that city, when a report upon the condition of Morocco was presented by Dr. Jannasch. The following particulars are extracted from the report in question. The industries of Morocco, from the European point of view, are in a somewhat primitive condition. There are no large factories, the only work in the various industries that are engaged in being performed by workpeople at their own houses. The work, however, turned out by these artisans is very remarkable, and testifies to their great skill in the treatment of the raw material. The art of the workmen engaged in preparing brushes and brooms, reed mats, mats and tissues of alfa, as well as alfa and palm leaf cordage may be considered to have reached a high standard of development. These articles are frequently made in different colours, and, in addition, many others are manufactured with considerable taste, such, for example, as hats of palm leaf and baskets of the same material, into which strips of leather are interwoven. Spinning is done in the towns, as well as in the country districts, by the hand-spindle, which is in use everywhere, but is not always of the same size. The yarn obtained is frequently of great fineness. It is only exceptionally that mixed threads are made, those of wool predominating. Among other uses, they employ these latter by hand-looms in making tissues of considerable beauty, and which resemble muslins. These are about five metres long and two metres wide, and are known as *hayaks*. With coarser and stronger yarns they make what are known as *djlacas*, a species of cloak with a hood. At Rabah excellent carpets are woven in natural colours, while in the majority of the other places of production aniline colours are used. The dyes employed in carpet manufacture are most frequently very glaring, but their effect notwithstanding is extremely harmonious. The greater part of the designs are excessively primitive. The leather industry is largely engaged in, and considerable quantities of harness and leather bags and pouches are turned out. For the latter articles various descriptions of leather of different colours are used, and the harness, as well as the bags

and pouches, are frequently ornamented with threads of gold and silver, and they are also richly embroidered. The Morocco slippers are well known, and have been for many years in Europe. Of these articles, Morocco exports about £40,000 worth to other countries in the North of Africa and to the east. The leather produced in Morocco is not equal in quality to the European article, and this is not because the tanning materials are defective, but in all probability because in the tanning itself certain substances are used which have the effect of diminishing the resisting power of the leather. Dr. Jannasch is of opinion that with the large number of hides which are at the disposal of the inhabitants each year, the tanning industry ought to attain a high degree of prosperity in Morocco. The earthenware industry is very extensively engaged in, and many articles of original design are produced. The red Fâs vases are very beautiful both in form and colour. They have frequently an antique classic shape, and are painted with cobalt and graphite, as well as with a particularly brilliant green colour. As regards the wood industry, those engaged in it almost exclusively use the Argan timber, which is as hard as iron and never becomes worm-eaten. The clothing trade is more frequently in the hands of the Jews—the greater part of the articles are made by women, who are very industrious.

BARCELONA EXHIBITION.

Further information respecting the International Exhibition of Reproductions from Artistic Industries of all ages till 1815, which was referred to in the number of the *Journal* for July 8, has been received. The Exhibition will be opened on the 24th September, and closed on the 26th December. All works sent for exhibition must be delivered at the offices of the Secretary of the Exhibition (Fine Arts Palace, Barcelona) before the 1st September, and must be withdrawn within ten days after the closure of the Exhibition. There will be a jury for admission, classification, and location of the works sent for exhibition, named by the Promoting Committee.

The Jury of Examination and Awards will be formed of the members of the Promoting Committee belonging to the Jury of the National Exhibition of Artistic Industries and of those elected by the Section of Reproductions. Non-resident exhibitors can take part in the election of the jury through their legal representatives. The prizes or awards will consist of medals of the first, second, and third class, with their respective diplomas. The jury will be empowered to award medals and diplomas to the artists, artificers, and workmen who, although non-exhibitors, may have specially excelled in the execution of the works rewarded, and to recommend them for a proportionate premium. Forms of application for intending exhibitors have been received, and a copy can be obtained on application to the Secretary of the Society of Arts, John-street, Adelphi.

Notes on Books.

A Letter to a Member of Parliament from Mr. William Murdock, in Vindication of his Character and Claims, in Reply to a Recent Publication by the Committee for Conducting through Parliament a Bill for Incorporating a Gas, Light, and Coke Company, London, 1809. Reprinted 1892.

This is a reprint by Mr. Richard B. Prosser of a very scarce pamphlet which has hitherto escaped the notice of writers upon the subject. Mr. Prosser in a Preparatory Note to his reprint writes: —"Murdock was represented before the Select Committee to whom the Bill was referred by Brougham, James Watt the younger appearing as Boulton and Watts' witness. Although it is often asserted that Murdock himself gave evidence, the Report of the Committee shows that this was not the case. The Bill was thrown out, but another Bill was introduced during the next Session and received the Royal assent on the 9th of June, 1810." In 1792 Murdock illuminated his Cornish home with coal gas made in an iron kettle burnt at the end of an open iron tube, and the present year is the centenary of the invention of gas-lighting. The reprint of this pamphlet by the inventor is therefore opportune.

Lessons in Commerce: A Text-Book for Students. By Professor Raffaele Gambaro; revised and edited by James Gault. London: Lockwood and Son.

The author, who is Lecturer on the English Language at the Royal High Commercial School at Genoa, intended his work principally for the use of Italian students. It bore the title of "Lessons on the Laws and Customs of British Trade," and was written in English, with notes in Italian. Professor Gault has made such alteration of the matter as seemed needed to adapt it for the use of English students. The various branches of the subject are dealt with in the following order:—(1) Commerce and trade; (2) mercantile persons; (3) companies and agents; (4) money, weights, and measures; (5) sales generally; (6) customs and warehousing; (7) carriage by land and sea; (8) average; (9) insurance; (10) bills and notes; (11) banking; (12) book-keeping; (13) stocks and stock exchange; (14) bankruptcy. One chapter is devoted to a series of tables of commercial abbreviations.

Encyclopedie Scientifique des Aide-Memoire. Publiée sous la direction de M.

Léauté, Membre de l'Institut. Paris: Gauthiers-Villars et Fils.

Recette, Conservation, et Travail des Bois, par M. Alheilig.

Distribution de l'Electricité. Usines Centrales, par R. V. Picon.

Analyze des Vins, par L. Magnier de La Source.

Thermodynamique à l'usage des Ingénieurs, par Aimé Witz.

Tiroirs et Distributeurs de Vapeur, par A. Madamet.

Le Divers Types de Moteurs à Vapeur, par Ed. Sauvage.

Notions de Chimie Agricole, par Th. Schloesing, fils.

La Bière, par J. L. Lindet.

These are some additional volumes of the engineering section of the "Encyclopédie Scientifique," previous volumes of which have already been noticed in the *Journal*. The different subjects are treated in a clear and systematic manner, and the various headings are distinctly printed. There are no indexes, but each volume has a full table of contents, and a list of books relating to the subject.

A Pocket-book for Miners and Metallurgists, comprising Rules, Formulæ, Tables, and Notes, for use in Field and Office Work. Compiled by Frederick Danvers Power. London: Crosby, Lockwood, and Son.

The author states that the collection of rules, formulæ, and tables which he has made has been found by him to be of use in the actual exercise of his profession, and he therefore hopes that it may be found of like service to others. Amongst other matters, this volume contains tables of weights and measures, and money, weights, dimensions, and properties of various articles, and information respecting heat, electro-plating, electrical units, electro-motive forces of various cells, motors, transmission of power, strength of materials, as well as data connected with chemistry, assaying, &c., mineralogy and geology, ore dressing necessary for the miner and metallurgist, and which can be put in a volume suitable for the pocket. Hints on photography, and a list of poisons, with their antidotes and remedies, are added.

Obituary.

Dr. Forbes Watson.—John Forbes Watson, M.A., LL.D., a member of the Society of Arts of thirty-four years standing, died at Upper Norwood, on the 29th July, aged 65. He was educated at the University of Aberdeen, and appointed to the Medical Service of the East India Company in August, 1850. He was appointed in 1858, by the Secretary of State, Reporter on the Products of India, and Director of the India Museum. He represented India at the International Exhibition held at London in 1862, Paris in 1867, Vienna in 1873, and at the South Kensington Annual Exhibitions 1870 to 1874. He retired from the India-office in 1880. Dr. Forbes Watson read a paper on the "Composition and Relative Value of the Food-grains of India" before the Society of Arts in November, 1857, and in March, 1859, one on the "Growth of Cotton in India." In May, 1860, he read a paper on the "Chief Fibre-yielding Plants of India," and in subsequent years he read several papers on the same subject, the last being on "The Preparation and Use of Rheea Fibre," read in December, 1883. Among other subjects brought by him before the Society were the "Extension of Commerce between the United Kingdom and India, and in the Development of the Resources of both countries by means of Trade Museums," a paper read in February, 1868, and "The India-office Museum Question," a paper read in April, 1875. Dr. Forbes Watson wrote and edited several works connected with the economic products of India, including "Textile Manufactures of India."

General Notes.

Artesian Wells in the United States.—From a recent bulletin issued by the United States Census-office, it appears that the total number of artesian wells on farms in June, 1890, in the States and territories forming the western half of the United States, was 8,097, representing an estimated aggregate investment of 1,988,461·26 dols. Complete statistics concerning the depth, cost, discharge, and other features of 2,971 of such wells, fairly distributed through the various States and counties from which they are reported, have been obtained from the owners, and from the averages derived from such statistics, the number of artesian wells used for the purposes of irrigation is computed at 3,930, the average depth per well 210·41 feet, the average cost per well 245·58 dols., the total discharge of water, per minute, 440,719·71 gallons, or 54·43 gallons per well per minute, the average area irrigated per well 13·21 acres, and the average cost of water per acre irrigated 18·55 dols. Over one-half of these wells are in the State of California, where 38,378 acres of agricultural land were irrigated by artesian water. Utah stands second in the number of artesian wells used for irrigation purposes, and Colorado in the area of land thus irrigated, followed, at a long distance, by Texas and other States.—*Board of Trade Journal.*

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

Journal of the Society of Arts.

No. 2,074. Vol. XL.

FRIDAY, AUGUST 19, 1892.

Chicago Exhibition, 1893.

OFFICES OF THE ROYAL COMMISSION.

The Royal Commission have received an intimation from Sir Henry Ponsonby that her Majesty the Queen has graciously given permission for the building which is now being erected at Chicago for the headquarters of the Commission to be called "The Victoria House."

EXHIBIT OF FOREIGN WOOLS.

The following letters have been addressed to the Hon. Walker Fearn, Chief of the Department of Foreign Affairs, by Mr. Buchanan, the Chief of the Department of Agriculture :—

Office of the Director-General,
World's Columbian Exposition,
Chicago, Ill., U.S.A.,
July 27th, 1892.

Department of Agriculture,
W. I. Buchanan, Chief.

My Dear Sir,—Through letters and inquiries reaching this office, I am impressed by the interest already evinced among the manufacturers of this country in the proposed exhibit of foreign grown wools, and other animal fibres to be made in the Agricultural Building.

I have assigned adequate space, and am figuring on designs for suitable cabinets for a display of the fleeces of all lanigerous animals, and in this connection beg to invite your attention to the importance of impressing the commissioners of foreign nations from which animal fibres are exported to the United States with the great commercial advantages certain to result from the fullest possible display of their exportable fleeces.

The countries most prominent in contributing to our supply of foreign wools are Australia, including New Zealand; Argentina, Uruguay, and Paraguay, in South America; Cape Colony and Natal, in Africa; Russia, England, Scotland, France, Germany, and Turkey, in Europe; Asia Minor, Arabia, and adjoining eastern countries. Recently, importation of wools from China and East India have largely developed, and met with ready sales among manufacturers of carpets and coarse fabrics.

In the mountainous portions of South America are produced large quantities of hairs from flocks of alpacas, vicunas, and llamas that are in constant demand, as are the fleeces of the Cashmere and Angora goats of Western Asia. As few of our people have ever seen these fibres in their natural state, there is no room for doubting that unusual interest will be taken in their display.

It occurs to me as highly important that the commissioners from each of the countries above named (or, if you think best, those from all foreign countries) should be made aware of the importance attached to the proposed display of animal fibres, and that they be urged to take immediate steps to do themselves justice. I am further satisfied that if the United States representatives in foreign countries can be induced to bring this subject to the attention of the Government to which they are accredited, satisfactory results are likely to follow.

Very respectfully yours,

W. I. Buchanan,
Chief, Department of Agriculture.

Foreign Fleece-bearing Animals.

August 1st, 1892.

My Dear Sir,—Supplementing my letter of July 27th, in reference to a display of foreign-grown wools and hairs, I have the honour to say:

The provisions made in that part of the Live Stock exhibit of the Exposition devoted to sheep and goats contemplate the presence of various unenumerated types of lanigerous animals possessing commercial and historical interest. This feature will depend for its success upon the interest taken by foreign countries taking part in the Exposition, as no premiums are to be paid for such animals.

I have in mind, as likely to be of especial interest to a large class of visitors, the fleece-bearing animals of South America. That is to say, the Mestiza sheep of Argentine and those of the Valley of the Rio Dedo Plata that produce coarse or carpet wools, also representative animals from the best fine wool-bearing flocks of Australia and of the cross-breeds of New Zealand. The flock products of all these countries have for some years supplied the severest competition that domestic growers have encountered in the home market, and I feel certain that extraordinary interest would attach to the presence of typical animals from which these competing wools are taken.

In Russia, Asia Minor, and throughout most of the Oriental countries, are numerous flocks of sheep of primitive types from which are supplied most of the sixty to eighty million pounds of carpet wools

each year imported into the United States. In view of the important commercial interests involved in this trade, I have confidence that typical animals of all the ovine races in eastern countries where our Government has representatives can be secured through the kind interest of foreign Commissioners to the Exposition, or our ministers.

In the mountainous sections of South America are herds of the alpaca and its congeners, the vicuna, llama, &c., many of which are made to serve the triple purpose of supplying fleeces for fabrics, furnishing meat for sustenance of the people, and doing duty as pack animals under conditions where even the ordinarily safe-footed mules cannot be utilised. In view of the cordial relations existing between this country and its South American neighbours, and the zeal with which these governments have responded to the invitation to join in the Columbian Exposition, I am confident that their Commissioners will be glad to send here from their countries one or more pair of their fleece-bearing animals.

Both Angora and Cashmere goats are liberally provided for in our premium list, and there is no room for doubt that the principal herds in this country will be well represented. It is greatly desired that alongside of these representatives from domestic herds we should also have specimen animals from the parent herds of Persia, Turkey, and other habitats of these useful animals.

I will be glad to provide necessary space, forage, and attendance for such animals above referred to as may be delivered to the Live Stock Department of the Exposition by foreign nations participating.

This department will be grateful for an early consideration of this subject by foreign Commissions interested, and respectfully asks for an early, and I trust, favourable reply.

Very respectfully yours,

W. I. BUCHANAN,

Chief, Department of Agriculture.
(In charge, Department of Live Stock.)

Proceedings of the Society.

CANTOR LECTURES.

DEVELOPMENTS OF ELECTRICAL DISTRIBUTION.

By PROF. GEORGE FORBES, F.R.S.

Lecture I.—Delivered January 25, 1892.

INTRODUCTORY.

In 1885, I had the honour to deliver a course of lectures here on the "Distribution of Electricity." This followed a long paper I had read to the Society of Telegraph Engineers on the "Heating of Conductors," when I got out tables for practical electricians of the sizes of wires to be used with different electric currents to prevent overheating. Up to that date, the distribution of electricity had been but little studied, and numerous serious mistakes were being made. My object at that time was to lay down in clear language the scientific conditions which must underlie any scheme of distribution. At that time, the more modern plan of using high tension alternating currents was hardly developed, and the advocates of high tension were engaged on storage batteries, and on various parallel-series systems, which introduced the high tension actually into houses.

When I arrived at the conclusion that, for a central station supplying 100,000 lamps, the copper conductors leaving the central station must, on the most economical principles, be equal to two cylinders of copper, each equalling the thickness of a man's body, it seemed that low tension was doomed.

No single invention of any importance has added to our facilities in low tension distribution, so as to affect the dimensions of the conductors, and yet low tension distribution has done much solid work on a large scale. When asked by the Council of the Society to give a course of Cantor Lectures, I felt that, at the present date, I could not do better than supplement my previous course, and bring my work on electrical distribution up to date; and it will be well also to examine the reasons why the objections which formerly existed against low tension distribution have so far been overridden, that millions of pounds sterling have been invested in it.

The present course of lectures is intended primarily for electrical engineers, and it is to them that my principal remarks will be addressed, but there are many present who have no intention of putting what they hear to practical use, and it will not be out of place if I indicate briefly some of the points that have to be attended to in electrical distribution.

The resistance offered by conductors to the electric current causes two sources of trouble. One is that energy is absorbed and wasted, and this may seriously affect the coal bill and the total machinery required in the central station. The solution of this difficulty is naturally to reduce the waste by reducing the resistance of the conductors. This means that we are to use larger copper conductors. But this increases the cost, and it is clear that there is a definite most-economical size, such that, if the con-

ductors are increased in size, the increased interest on capital expenditure swells the cost; and if we diminish the size, the extra machinery required increases it, and the coal bill rises. It is an important function of the electrical engineer to determine in every case this most economical size of conductor. Large experience has generally led to finding the most economical size to be such that the current density shall be not more than 500 ampères per square inch. The other trouble is that when many lamps are in use, and a large current is flowing, the electric pressure is reduced and the lamps are dim. The further distant a lamp is from the central station the lower is its pressure, and the difference in brightness of lamps is particularly observable in the distant lamps. Those near the station suffer no loss. To increase the brightness of distant lamps during the busy hours, the pressure at the station may be slightly raised. Thus we generally find in central station distribution that in the busy hours lamps near the station are brighter than usual, and the distant ones are more dim. This is well shown by diagrams of pressure taken on different parts of distribution mains by self-recording apparatus. This solution of the trouble does not go far, however, as we cannot allow a large variation of pressure in any lamp. The Board of Trade at present allow the large fluctuation of 8 per cent., and it is to be regretted that the supply companies generally avail themselves to the full of this latitude. This is shown by recording volt-meters.

For further improvement in the supply it is necessary to introduce feeders, which are conducting wires going from the central station direct to certain points on the network of distributing mains, where the variation in volts is found to be large. No lamps being connected on to the length of these feeders, the full pressure can be supplied at the point of distribution without other lamps being raised in pressure.

I do not intend to pass further in review the general principles of low tension distribution. The problem and the rules to be followed were completely worked out in detail in my previous Cantor Lectures; and after these seven last years of busy work, I have not one word to alter in all that I said at that date.

Nor have I the intention in the present course to do what might be an interesting proceeding, viz., to describe the various central stations which have been erected in these years, and analyse and criticise their modes of working. Some of the stations with which I have myself been connected as consulting engineer have been low tension and some high tension, and it might have been thought desirable that I should give you the results of my own experience. Moreover, as is well known, I have largely devoted myself to a careful study on the spot of a large proportion of the central stations both in Europe and America, and I might easily have found materials in this experience to occupy a few evenings with profit. I have, however, other aims in these lectures, and descriptions of central stations are not wanting to those who are sufficiently interested in them. I have myself given full details of the machinery and methods employed at some of the great European stations in a paper read before the Institution of Electrical Engineers in 1889. A very interesting account of central stations in Germany, by all the best manufacturers, was brought out in a handbook published last year at Frankfort for the Exhibition.* My desire is to carry into these lectures the same spirit that led to my previous Cantor Lectures, and to bring before engineers the points that require attention to make our work as perfect as possible, and to draw attention to the lines in which we may hope to overcome the great drawbacks which still hamper the industry, and prevent it from furnishing such economical results as the general conditions of the problems warrant us in expecting. It will, I hope, be found that there are engineering resources at our call which have yet to be invoked before we have reached the final solution of the problems.

As an example, I will point out to you one or two facts in the economy of the subject. One is that central station distribution, as distinguished from isolated plants, involves a huge additional expense in distributing mains. The cost of these must, from the nature of the case, be out of proportion to their earnings until the consumers are much more closely packed than at present.

Another fact is that our machinery is lying idle three-quarters of the year, and earning no dividend. A third is that, owing to the limited period during each day that the maximum demand exists, we waste fuel in heating up most of our boilers for only a couple of hours' work in the evening. A fourth point is that, owing to the irregularity of the demand, we waste a a great deal of steam by working our engines much under their full and economical load.

* Die Versorgung von Städten mit Elektrischem Strom.

All these points will be fully elaborated in the lectures. The net result is that electricity in London costs twice as much as gas, that it costs more to obtain it from a public supply than when manufactured (for a large establishment) on the premises, that the method of debiting consumers is unfair on those who have the longest hours of working. You must not be deceived by the optimistic calculations of enthusiasts and interested parties. The electrical industry has nothing to fear from competition, and the surest way of gaining the confidence of the public, and of making sound progress, is to openly accept the true state of the case, and acknowledge the difficulties that hamper you, and then apply all the skill at your disposal to overcome these difficulties. In illustration of the points I have raised, I will here only state one or two points.

1. The streets in London are not lighted generally as they ought to be by arc-lights. We know, from a most extensive experience, that anyone can set up a circuit of ten ampère arc lamps with underground mains, and run them with good profit at a rate of £30 per annum, during all the hours that gas lamps are now used (4,000 hours per annum). The cost of the mere current for these from a supply company, at 7d. per unit, amounts to £58 6s. 8d., double what it would be if privately worked.

2. A careful comparison of the cost of lighting the Athenæum Club with its own machinery, which has been done for many years, with the charges from a supply company at 7d. per unit, shows that the present cost is £894 per annum, including depreciation on machinery costing £1,608, as against £1,452, which the company would charge us.

We must fairly recognise the fact that electricity is twice as dear as gas, and also that where we replace gas by electricity we must increase our expense in warming a house. When this has been granted, we must remember that we save much in decorating and in preserving our books, that we abolish vitiated and dirty air, and that we can keep our rooms cool. These are sufficient recommendations for those who value cleanliness and health, and will spur the ingenious among us to remove the confessed drawbacks.

In order to perfect our systems of distribution in practice, we must keep before our minds the ideally perfect, and depart from that course only at the gain of decidedly practical advantages, and we shall often find that, if due caution is exercised, we can gain much by very slight departures from the ideally perfect. This is the spirit which has actuated the evolutionists of the modern dynamo, and which enables us to be proud of our 96 per cent. efficiency, while the steam-engine, with a hundred years of brain work and millions of money spent on its development, has reached only 80 per cent. efficiency in its mechanical working. Had it not been for the scientific men who took up dynamo construction at the beginning, we would have rested content with the 50 per cent. efficiency originally offered by Brush and others in machines which were thoroughly well designed mechanically, and did their work thoroughly, if uneconomically. At first, designs of complicated character were introduced, in which the rapidly revolving parts, those requiring most mechanical strength, contained only the following materials:—An iron spindle, a wooden hub, and an armature made of iron wire, wound with copper wire, the parts being joined and separated by millinery and paper and sealing-wax. The object of this construction was to minimise the losses. One weak part after another was discarded, until we now have a fairly strong and mechanical armature.

So in electrical distribution. Ten years ago we searched for the ideally best. In each case we made elaborate calculations of the probable consumption in different parts, and we tried to average the relative size of feeders and distributing mains and their points of connection as accurately as possible. We tried to select those points for attaching feeders that would use the least copper, and we tried to devise means of regulating electric pressure in the feeders, so as to waste no more copper or electric energy than was absolutely necessary.

Ten years of practice in central station working has now stereotyped our practice a good deal; and while we do not always lead a conducting wire by the shortest route from each lamp to the central station; and while we do not always attach a feeder to the nearest part of the district it has to feed in normal conditions, still we always have these leading principles in mind while laying out a plan of electric mains, and we readily adopt the general average results of our experience in past work to simplify our system.

Central Station Supply *versus* Isolated Plant.

At the date of my previous Cantor Lectures

the great question before our minds was whether central stations were economical. It was obviously far more convenient for the public to be supplied from a general source than for each one to generate his own electricity; in fact, the latter plan would be impossible, except in the case of large establishments. It was further obvious that the cost of both labour and coals in small plants would be far greater than in a central station. But the fact remained that, with central stations, we had all the additional cost of mains run through the streets, involving enormous cost, not only in copper, but also in taking up streets, finding a way among all the underground pipes, and making all good again. We had just learnt, from the experience of the telephones, that the more subscribers there were after a certain limit, extending to greater distances, the less dividends could be paid. Consequently, there were many men at that date who did not think that central stations could compete against isolated plants for even moderate-sized establishments, and who saw no prospect of small consumers being supplied, except by neighbours clubbing together to generate electricity for themselves.

Fortunately the verdict has hitherto generally been that current *can* be economically generated in, and distributed from, central stations, and the proof is in the enormous ramification of electric circuits now occupying the beds of the streets of London. I do not know the case of any town in the world where such enormous progress—designed for permanency—has been made in so short a time. From 1882 to 1889 the legislative enactments restrained and held, as in a leash, the spirit of the age (which is electrical). In the last-named year, Major Marindin, acting for the Board of Trade, held the great enquiry in London, besides minor ones in other towns, as to what powers were to be granted to what companies. From the moment that his reports were accepted, the forces which had so long been restrained burst forth, and the pioneers, like released greyhounds, darted after their prey, and the whole place was in the hands of the electricians. All the work was well done, and will remain; and we may well be proud of what has been accomplished.

But while thus congratulating ourselves, we must not overlook the fact that we are prevented by several causes from supplying electricity so cheaply as might be hoped. I have already given you the figures with respect to one large club, and I could give you many others to show that at present, for a large establishment using light for long hours, an isolated plant is the cheaper. It is particularly to be remarked that the average number of hours that a light is in use is barely two hours a day. Hence, during the greater part of the twenty-four hours, the mains in the street are lying practically idle, the boilers and engines are earning no dividend, while the managing staff would have no more work if all the customers used the light for longer hours. Hence, during the greater part of the day, the cost of producing an additional electric Board of Trade unit is little more than the cost of the coal, certainly not 2d. a unit, while for a few hours in the evening it is at least three times as much. You see, then, how hard a fixed price per unit is on clubs and other places where a steady large supply is wanted for long hours. This is one reason why the public supply to the Athenæum Club would cost £500 more than the cost of making it on the premises. This is why the cost of an electric arc-lamp for street-lighting would be double what it would if not obtained from a supply company. If we had any means of supplying electricity for a short time as cheaply as at the full output all the twenty-four hours, we should reduce the selling price to one-third of what it is now.

Electricity *versus* Gas.

At the present time, electricity in towns often costs twice as much as gas, and it is not everyone who can see that the gains counterbalance the extra expense. It certainly saves expense in decoration, it is far more healthy, and in valuable buildings like the British Museum, it alone can be permitted, as giving absolute immunity from fire where properly carried out. The same remark applies to all private houses. When a curtain or a dress is blown by the wind or otherwise brought into contact with a gas jet we have a fire. When this happens with an incandescent lamp we have absolute immunity. But by taking advantage of the facility of putting out a light in a bedroom when done with, great economies can be effected in careful households. There is one case in which electricity beats gas and other illuminants, not only in cleanliness, health, and security from fire, but also in economy, and that is in country houses. I could bear this out by numerous examples. One large old castle in Scotland, where the risk of fire was great, and the electric light was introduced primarily for security from fire,

offers a good example. Here there are 210 lights of 16 candle-power installed, the house has always been full, and the lights much used. The installation cost £1,800, and last year, the second of working, an accurate note of all the expenses, labour, coal, &c., comes to £75. Nothing approaching to this could have been got from gas manufactured on the premises, and, at the rates charged by supply companies, the cost would have been over £300.

Feeders and Distributing Mains.

The satisfactory working of a central station depends largely on the proportion that the feeders bear to the distributing mains. Some stations have been started by persons quite incompetent to do the work, and have no feeders

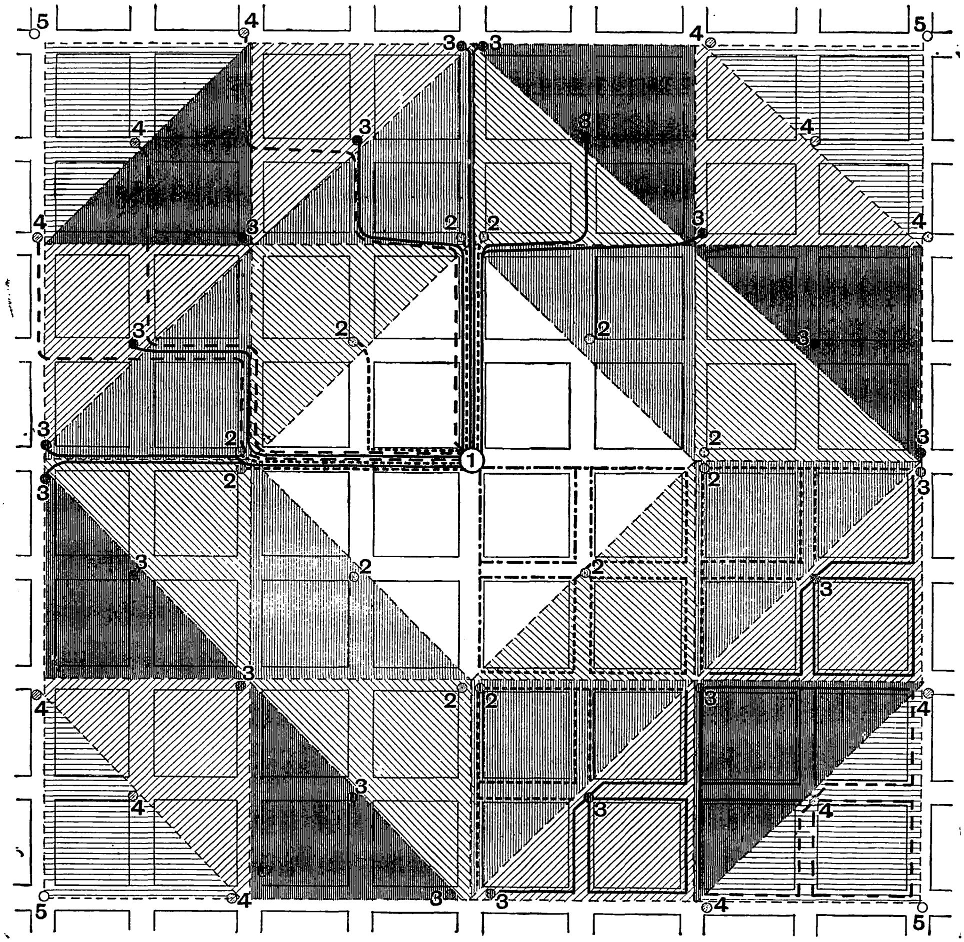

Fig. 1.

at all. The consequence is that we have enormous variations in the pressure at different times. I believe that at Brighton there is at times of maximum working a difference of pressure in lamps on different parts of the circuit amounting to 25 volts, and instead of applying the well-known engineering methods, it has been attempted to patch it up by putting lamps of different voltage on different parts of the system. When such a thing is attempted, except for the correction of a very few volts, we are landed in worse trouble. I would draw attention to the diagram on the wall (Fig. 1) representing the plan of an American city like Philadelphia, and showing the way in which the feeders and distributing mains would be run for lighting the city with economy, and confining the variation of pressure all over it within the same limits. The centre square, shown white, would have no feeders, but be

divided up into four triangular-shaped districts, each being supplied by mains from the central station. The part between the feeding points marked 2, and those marked 3, would be divided up in the same way into triangular-shaped districts, and each have its own feeder, and distributing mains starting from a No. 2 feeding centre; and so on for the districts outside these. It will be noticed that all the distributing mains starting from the feeding points are of equal length, if measured along the streets, as shown at the bottom right-hand corner of the diagram. The circuits being run in this way, a network may be formed by connecting the ends of the distributing mains together wherever close, and whichever district they belong to, since the pressure at these points will always be nearly the same, assuming the same current density in all the distributing mains, of course. I sent out a circular lately to try to find out how far the benefit of feeders was appreciated in our central station engineering, but very few supply companies cared to give the information. I find that the Kensington and Knightsbridge Company have—

	tons.	cwt.	qrs.	lbs.
Total weight of mains........	133	11	3	5
Total weight of feeders........	15	10	3	0

in a total length of street covered = 12 miles 835 yards; partly copper strip, insulated by glass insulators, supported by oak bars, being used; and partly vulcanised rubber cables run in iron gas pipes coated with Angus Smith's composition.

The cost for straightforward work under foot pavement, including material, wages, superintendence, digging, and carting away, but not tocls and spare plant, is stated to be—

	Per Yard. £	s.	d.
5 pipes, 4 of 2-in., and 1 of $1\frac{1}{2}$-in., with 3 cables $\frac{61}{15}$s, and 2 cables $\frac{37}{10}$s.	3	2	2
3 pipes, 2 of 2-in., and 1 of $1\frac{1}{2}$-in., and 3 $\frac{61}{15}$ cables	1	8	$6\frac{1}{2}$
15-in. culvert, including 3 strips 1-in. × $\frac{1}{4}$-in.	1	3	9
20-in. ,, ,, 5 ,, ,, ,,	1	9	0
24 in. ,, ,, 7 ,, ,, ,,	1	14	2

The number of lamps supplied up to January 6th, 1892, is equivalent to 38,680 of 8 candle-power.

The horse-power available is—

Kensington-court	1,070
Chapel-place	700
	1,770

The total capital invested in mains of all kinds, including copper and cable, is 33 per cent. of £133,000, the total paid-up capital; in machinery and buildings, 43 per cent., and in batteries 10 per cent.

At Chelmsford, with alternating currents, overhead wire is generally used, $\frac{3}{4}$ ton for street lights, $1\frac{1}{2}$ ton for secondary wires, and 1 ton for primaries for private lighting. Indicated horse-power in station, 300; total outlay, £14,000. Lamps, 220 of 32 candle-power, 1,000 of 8 candle-power for private use, 19 arcs of 10 ampères, and lamps in works using 180 ampères and 110 volts. Welsh coal per unit generated, 8 8 lbs.; efficiency of an engine and dynamo, 75 per cent. (mean).

The Westminster Electric Supply Corporation's distributing mains are estimated roughly at two to two and a-half times the weight of the feeders. The total capital of this Corporation is £300,000, the total indicated horse-power in central stations 3,500, and the number of lamps supplied equivalent to 66,000 8 candle-power. The cost of mains and underground work is roughly £150,000, and the total length of pavement opened up is 53,640 yards. In places, the mains consist of bare copper in concrete culverts; but the Corporation have by far a greater length of insulated cable laid in Callender casings.

The Northampton Electric Light and Power Company have equal weights of distributing mains and feeders. The capital invested in mains is 42 per cent. of the total capital of the company, the length of mains 2,800 yards, including 350 yards of feeders only, and the total weight of copper 16 tons. The mains consist of bare copper in Crompton culverts, where possible; Henley's AA cable in 2-inch iron pipes at road crossings, &c.; Fowler-Waring cables, lead-covered, laid in half glazed-pipes with sand, and covered with concrete, and Callender cables in iron troughs and bitumen, for isolated feeders. The average cost of mains is 45s. per yard. The indicated horse-power at work is 240; 120 additional being on order. The number of 8 candle-power lamps supplied, 33,000. The proportionate cost of buildings and machinery, &c., to paid-up capital is—buildings and machinery, 46 per cent.; land, 5 per cent.; the paid-up capital being £15,000.

Another company, with paid-up shares and debentures = £73,585, whose expenditure on mains is £17,440, has 20 miles of cable in 6 miles of street, consisting of $20\frac{1}{2}$ tons of copper for feeders, and 28 for distributing

mains. Actual cost of supplying and laying Callender-Webber casing with three 2-inch ways, including all charges, with straightforward work = 6s. 6d. per yard, or including the draw and service boxes, 8s. 9d. per yard run. The lamps = 28,000, of 8 candle-power; and there is 830 horse-power in the central station in the shape of steam-engines alone.

The Allgemeine Elektricitäts Gesellschaft has over 700,000 metres of copper, weighing 1,500 tons, nearly all in Siemens' armoured cable, costing from £2 to £4 10s. per yard. This enormous mass of copper accounts for the splendidly constant pressure always maintained in the network.

The Secteur Clichy, in Paris, cover 26 kilometres of street with 31 kilometres of feeders and 121 of distributing mains.

The cost of laying 3-inch iron pipes in cement in New York, with man-holes 7 feet deep, 8½ feet square inside, with 12-inch walls of brick in cement, depends on the number of ducts, and is as follows:—

No. of Ducts.	Dollars per Duct per foot run.	Shillings per yard.

The average cost of a house connection, from a large number of actual cases, is $66·02, say £13.

These special cases are given as a small contribution to the general question. My own general experience is that mains ought to cost, on the low-tension system, about half the capital of the company, about equally divided in distributing mains and feeders. I think that far more copper would be put down in mains if people realised the low rate of interest at which money could be raised in debentures on them.

Experience is the best guide as to the proportion between feeders and network mains. The smaller the latter, the more numerous must the former be. The distance that can be covered by a feeder depends on many things, but firstly on the variation in pressure allowed at the house connections. The Board of Trade, wisely I think, has given great latitude, 4 volts either above or below the normal 100 volts—*i.e.*, an 8 per cent. variation—but it is to be hoped that supply companies will find it to their interest to attain a higher standard. If the feeder point is kept at a constant pressure of 100 volts, the 4 volts will be lost in 80 yards if the section of copper is based upon a current density of 1,000 ampères per square inch, or in 240 yards if 330 ampères per square inch is chosen; and I am glad to say that in this country a large section like this is recognised as the best design. If now we use a three-wire system, we can go to twice the distance, or 480 yards, with a current-density of 330, still with a maximum drop of 4 volts. If the pilot wires which indicate pressure be not at each feeding point, but half way to the most distant lamps supplied by a feeder, the length of main which can be fed is again twice as great, or 960 yards, the lamps at the feeding points varying from 100 volts at times of small demand, to 104 at the maximum, the lamps at the distant end varying from 100 volts at times of small demand, to 96 at the maximum. If now the lamps at the feeding points be 104-volt lamps, and those at the distant end 96-volt lamps, with graduated voltages at intermediate points, we can increase the length of main supplied by a feeder to 1,920 yards, and no lamp will have a greater variation than 4 volts above or below its normal value. Of course this result has never been attained in practice because in most cases it is difficult to accomplish. I do not generally approve of using lamps of different voltage on a circuit. The only time I ever sanctioned it was when I settled what was to be done by the St. James's and Pall-mall Company. Here the district was so compact that I could see easily that we would not be bothered by the future extensions. There is also some trouble in putting the pilot wires in the place indicated. There is also some difficulty in arranging the feeders so that they all feed into the network at the required pressure. Some engineers are also afraid of the three-wire system, having had no experience of its use. And, again, in a badly-fitted station, it is difficult to ensure that the engines are working quite uniformly, so that a 2 per cent. variation, up and down, may be all that can be calculated for in order to conform with

the Board of Trade requirements. All these reasons may reduce the workable distance, even when the low current density here assumed is taken, from the above 1,920 yards down to 240 yards. I wish to impress strongly on you the fact that there are four distinct methods of improving the distribution—(1) increasing the regularity of the engines, (2) using the three-wire system, (3) putting the pilot wire connections half way between feeder points, and (4) varying the voltage of lamps according to the distance from a feeder point. The last is the only one which cannot be safely done in all cases, and each of these four remedies enables us to go to double the distance, the introduction of the three-wires being the only one which increases the weight of copper a little; or we may say, especially with relation to the position of the pilot wires and the voltage of lamps, that these remedies each halve the weight and cost of copper in the mains, and, combined, reduce it to one quarter. The practical objection to using lamps of different voltages is that generally the network is first laid down and the feeders added in greater number as the demand increases, hence the voltage of lamps in any house will be changed. But the improvement on existing methods which I have advocated, of putting the pilot wire attachment half-way between feeder points, saves half the copper and can always be applied.

Management of Feeders.

In the central station the arrangements for supplying the feeding points with the same pressure are not always satisfactory. It has been customary in many cases to make the resistance of each feeder the same, so that when the same current is flowing in each the fall of pressure along the feeder is the same. Other people use adjustable resistances to regulate the pressure. In both these cases omnibus bars can be used to connect all the dynamos in parallel and all the feeders in parallel. This is very wasteful. Another plan is to use the dynamos at different pressures, and group the feeders on them according to their requirements. This is perfect in theory, but difficult in practice. It involves frequent shifting of a feeder from one dynamo to another, and it involves engines running at low loads. Another plan has been suggested, to put in a few secondary battery cells in the feeders in place of resistances, some to raise and others to lower the pressure, according as they assist or oppose the current. The two volts given by such cells is a convenient unit for such a purpose. The best plan seems to me to be one which has not hitherto been adopted. Connect all the dynamos in parallel on omnibus bars. Between this and the feeders put switches, by means of which one or more low-tension dynamos (of two volts say) can be switched in to assist or oppose the current. I would not suggest this were I not now thoroughly satisfied with the low-tension non-commutating dynamos with which my name has been connected. To show their suitability, I will merely record an experiment with one of these dynamos used with a Parsons's steam turbine. The armature was merely a solid bar of wrought iron, 3 inches in diameter, and it rotated between two magnet poles, which enclosed it, at a speed of 24,000 revolutions a minute. With this we welded pieces of iron $\frac{5}{8}$-inch diameter, and then heated a rod of $\frac{5}{8}$-inch iron, 15 inches long, to a white heat for an hour and a half, and everything was working quite smoothly, and could have gone on like that for twenty-four hours. The E.M.F. on open circuit was four volts, and on closed circuit two volts.

Loss in House Wiring.

I hope that, before long, the Board of Trade will reduce the variation now allowed of 4 per cent. up and down to half this amount. There is always a certain loss of pressure in the house wiring, which ought never to exceed two volts. But as householders seldom engage an electrical engineer to protect their interests against the contractors, the latter generally use thinner wires than is right, and so reduce the pressure in the lamps still more. A variation of more than 2 per cent. from the normal pressure at the lamps is very objectionable in practice, though I suppose we must put up with it for some time.

Recording Voltmeters.

I will now show you some results of actual work. I have on the table one of the recording voltmeters made by Messrs. Richard Frères. It is like the well-known recording aneroids. A cylinder is revolved by clockwork and carries a ruled sheet of paper; while the paper travels horizontally, a voltmeter causes a pointer filled with ink, and just touching the paper, to rise and fall with the electric pressure, and thus we get a continuous record of the pressure which a house is receiving from the supply com-

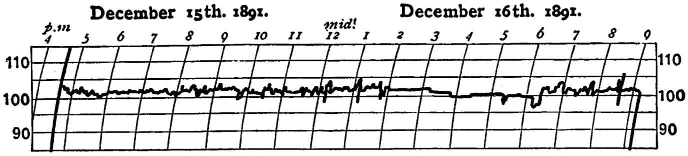

FIG. 2.

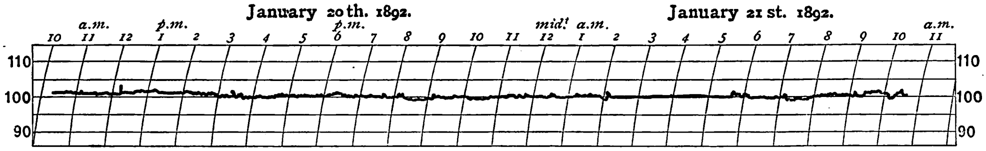

FIG. 3.

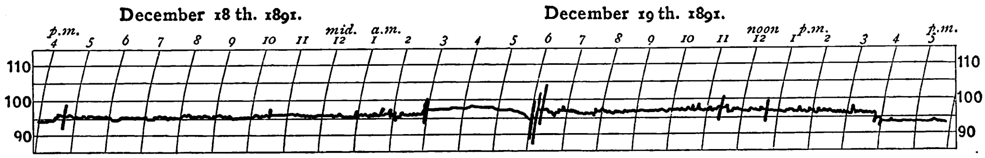

FIG. 4.

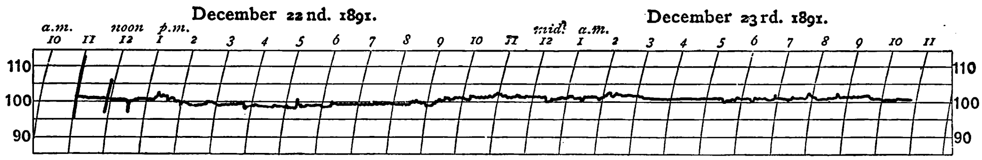

FIG. 5.

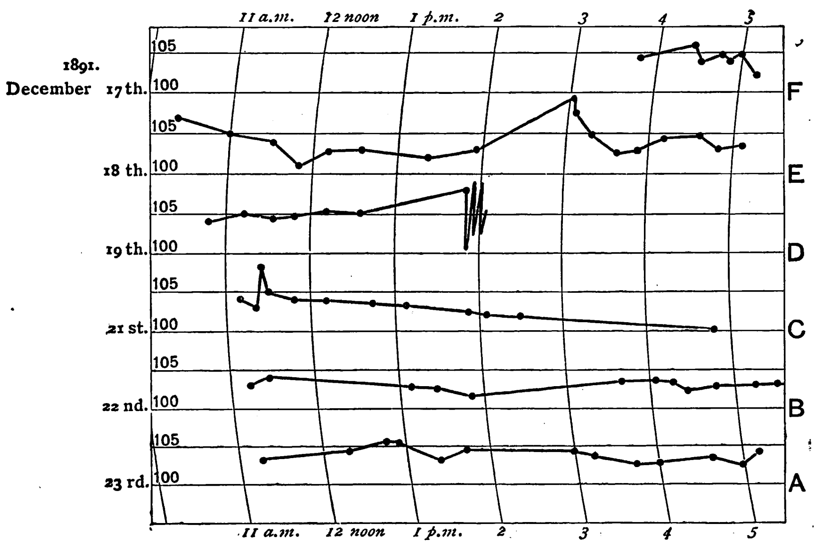

The divisions AB, BC, CD, DE, EF respectively represent 10 volts each.

FIG. 6.

pany. This instrument is very convenient and useful. The one I have been using is made to work up to 120 volts, and its range of greatest accuracy is at half this pressure. The controlling force of the magnet is weak at 100 volts and the friction of the paper comes into play to diminish the actual irregularities. Still I have been able to obtain interesting curves in a variety of places; and I wish to draw the attention of administrative bodies like the London County Council to the necessity of using such instruments in the interests of the community, and as the only real check upon the supply companies. The instrument which I have used reads low at 100 volts. I have a number of curves taken at four places on the mains of one supply company, and except at one place they come out very nicely, only we must remember that the full irregularities are not shown by this instrument. The places of which records are shown are my office, at 34, Great George-street, 39, Victoria-street, 13, Ashley-gardens, and the Scottish Club in Dover-street, Piccadilly. [Some of these curves are here reproduced (p. 870). Figs. 2 and 3 are records taken at my office in Great George-street; Fig. 4, one taken at the Scottish Club; and Fig. 5, one from Ashley-gardens.] To show the real irregularities, I have added drawings from actual observations at frequent intervals of an accurate voltmeter, when you see (Fig. 6) that the pressure in my office is always high, and sometimes reaches 109 instead of 100 volts. Of course this is very destructive to the lamps, and renders the company liable

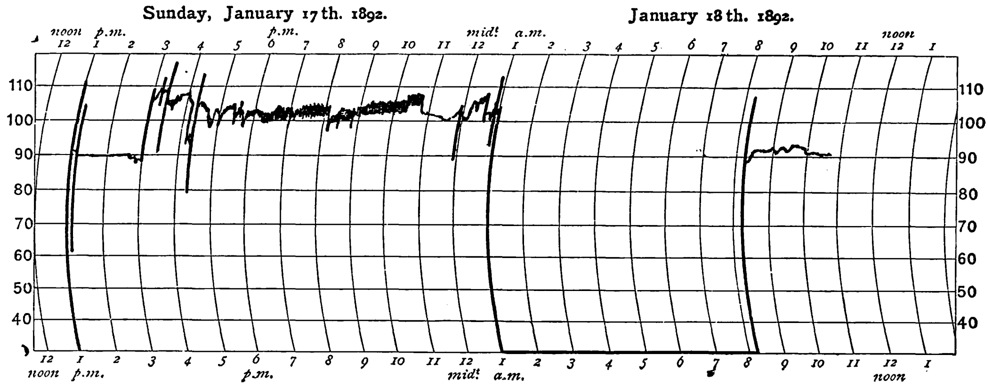

FIG. 7.

to fine. The pressure at this part of the distribution system is always too high, and apt to injure the lamps. At Dover-street, on the other hand, the pressure is always too low, and the illumination is bad. When the busy evening hours come on, the pressure at Dover-street always falls. The influence of a fog is shown in the same way. It is not to the interest of a supply company that such defects should go on. While exhibiting these curves, I add one taken at the Athenæum Club (Fig. 7), which is supplied by a gas-engine and dynamo of its own, with accumulators as regulators, and for use during slack hours. Notice the violent irregularities, simply owing to the carelessness of the attendant, and also notice the effect of the pulsations of the gas-engine, showing a pulsation of 2 or 3 volts, which goes on every second or half-second, and is most trying to the eyes.

FIVE-WIRE SYSTEM.

The evident advantages of the three-wire system can obviously be extended to a greater number of wires, if we do not object to bringing the higher electric pressure into our houses and up to the lamps. This has been done with five wires, by the company lighting the Secteur Clichy at Paris, and in other places. Since five wires here take the place of eight, the advantage is greater than when three wires take the place of four. By using it we can also go to twice the distance of the three-wire system. I shall have something to say about this method in my next lecture, to which it is more suitable.

BATTERIES.

I must conclude this part of my subject with some mention of a class of electrical apparatus which has been improved more than anything else in connection with low-pressure supply since I gave my previous Cantor Lectures. The position which I then took up was this, that there was no plan for electric lighting so satisfactory as the secondary battery plan, but it was hopeless to think of it until one important element was invented, namely, a practical secondary battery. That *desideratum* is much nearer realisation. In the last ten years dynamos have been much improved, and so have lamps, but in no branch has the improvement equalled that in secondary batteries.

These improvements are partly in the way of making the plates more substantial, and less liable to buckle or scale, or for the pellets to drop out, and partly in their management, the chief step in the latter direction coming from the discovery that batteries will stand any amount of overcharging, and really improve in the process, and also that they should never be allowed to run down, and that low specific gravity should be remedied by persistent overcharging, recourse to adding acid being only resorted to at rare intervals. To keep batteries in a high state of preservation in this way involves great expense, from the frequent overcharging, and also from the fact that, if we never take much out of the battery, we must have a larger outlay in them to do our work. At the present time, the only objection to batteries is their expense, and that is now far less serious than six years ago, when their life was very short. Secondary batteries are often called accumulators, or storage batteries, according to the purpose for which they are wanted. They are used for five different purposes—(1) As regulators; (2) to replace dynamos, and give workmen a rest at idle hours; (3) to add to the total out-put of a central station at a time of maximum demand; (4) as a reserve in case of breakdown, and (5) to transform down from high pressure in the streets to low pressure in the houses. All these are most useful purposes and seem so desirable that many companies have adopted them even at a greater cost of supplying the electricity. Of course you will always find the manufacturers of any such special plant saying that it does not increase the cost to use it, and when, as often happens, the manufacturer acts also as consulting engineer, you may expect the use of such plant to be more extensive than their costliness warrants. This has been the case in England in many cases, but it is not to be regretted by the general public, because these cases have given us much valuable experience. In this year, 1892, however, the improvements in storage batteries are such that it hardly costs anything more to use them than to do without them, and we see the desirability for storage of some kind in our central stations so much in actual working, that we may hope the time will soon come when some kind of storage will be possible for a large part of our generating plant, so that we will not require to fire up a lot of boilers just for a few hours work. When a battery is put across the mains at the central station it acts as a regulator, and keeps the current steady in spite of irregularities in the engine. This ought not to be an important point in central stations, but it is in isolated plant worked by a gas-engine. The battery in the central station, however, offers a splendid means of regulating the pressure in the feeders, which can then be supplied at any pressure with current, and the size of copper can then be chosen to fulfil the economical law of being proportioned to the current, and not to the barbarous law of making the resistance of all feeders equal. Much discussion has arisen about the value of accumulators in central stations, but it is remarkable that, up to the present time, the one great advantage has been overlooked, which is that you can use them in shunt on the mains as a means of regulating the pressure supplied to feeders. This action is the only solution that has been tried which gives perfect satisfaction. I do not believe that the introduction of accumulators into a central station has ever introduced economy, but in many ways it leads to a better service, and in no way more than in this which I have just indicated. So much is this the case that, except in the few cases where economy overrides quality of light, or in some cases where a fall of water is the source of power, I do not think that any low-tension continuous current central station on a large scale is complete without a small supply of accumulators. The other use of accumulators as transformers of high pressure into low pressure belongs to the subject of my next lecture.

CANTOR LECTURES.

DEVELOPMENTS OF ELECTRICAL DISTRIBUTION.

By Prof. George Forbes, F.R.S.

Lecture II.—Delivered February 1, 1892.

In my last lecture I urged the importance of not slurring over the actual difficulties that are before us. We are looking at the question of distribution from an engineering point of view, and it is desirable always to face the difficulties and see our way as far as possible, rather than to slur them over and pretend that they do not exist. Now, I pointed out the chief causes of excessive expenditure in electrical distribution through towns. They are two—first, the cost of distribution; second, the cost of generation. In both of these cases of production and distribution the expense is greater than it would be if we were producing it for our own purpose at a constant rate. Distribution is particularly expensive at the present moment, because there is only a small number of houses connected. Mains are being laid through great lengths of street, and perhaps only one in thirty houses is taking current. That will mend as time goes on, and that cause of excessive cost will diminish in consequence. The other great source of expenditure that any supply company has to face, lies in the fact that electricity is not wanted uniformly throughout the 24 hours. This is, perhaps, the most important point to which attention has been drawn of late years in the question of distribution. It injures us in two distinct ways — first, through our engines; secondly, through our boilers. Owing to the fluctuating demand for light, we are compelled to vary the number of engines which are working to supply the mains; and employ the engines sometimes at below their economical load, and that is extravagant. Besides this, the boilers consume more fuel than if a continuous supply is given, because so much coal is spent in heating them up in the evening. With regard to light loads of engines, few people realise what enormous loss there is when we are running powerful engines at light loads, more especially compound engines. It is quite possible that a 100 horse-power engine, which would be consuming (say) 22 pounds of water or steam per indicated horse-power per hour when running at full load, would, running at light load —one or two horse-power—be consuming as much as 600 pounds of steam per horse-power hour. This great source of loss could be got over by having the units in the way of engines tolerably small. The smallest size of engine is efficient, so that by employing a number of them, and putting them on in turn, we never have much loss through under-loading; but with respect to boilers, we are without remedy at the present time. Great attention was drawn to this point in the paper read by Mr. Crompton before the Institution of Civil Engineers last year, in which he introduced the term, "load factor." Load factor is a very important thing, but the one peculiar thing about it is, that no one knows what it is. Mr. Crompton introduced five distinct definitions of the load factor, each of them giving a totally different meaning to the other cases where the words are used without alluding to what is meant. I will give you a series of definitions, which, I trust, will suffice for the future. I had hoped that Mr. Crompton would have given us an exact definition, but he has failed us in that, and, therefore, I will give you what I think will be sufficient for engineers.

I will draw attention to these diagrams which belong to the Berlin station.* The heavy load lasts only for a few hours. The thick white line indicates the load which is passing out. During the winter months, at about six or eight in the morning, a small peak is shown. There is nothing else till the afternoon, when it rises to its maximum. The same general features prevail throughout the year in the different months, except in the mornings of the summer months, when the demand for

* These diagrams are published in a paper read by Professor George Forbes before the Institution of Electrical Engineers, 28 February, 1889, on "Some Electric Lighting Central Stations in Europe, and their Lessons."

current ceases, and in the summer months the height of the peak diminishes, and the number of hours. Similar curves have been taken in many other central stations, and I would refer to a similar set of great value relating to the St. James's and Pall Mall Company's station, which are published in *The Electrician* of January 22, 1892, and which show the same general fluctuations as the Berlin curves. There are two consequences to be noted from this great irregularity in the demand. In the first place, owing to the high peak that we have during winter, we must have a large amount of machinery ready to take part in supplying current; in the summer months a great part is not in use; and during the day, even in winter, a great portion of our machinery is absolutely idle. It is in this way idle for the greater part of the year. In the second place we have to fire up our boilers during the slack hours, just before the rise, so as to be able to cope with the demand at the busiest hours, which means waste.

That being the general state of things, let us come to actual definitions about "load factors." Mr. Crompton tried to indicate that it was the ratio of the average quantity of electricity to the maximum, but what maximum was to be chosen for the whole year was not defined. I propose to adopt three distinct definitions—the machinery load factor, the current load factor, and the temporary load factor. By the machinery load factor for any period, I mean the ratio of the average current during that period to the maximum current obtainable from the machinery. By the current load factor for any period, I mean the ratio of the average current during that period to the maximum current ever supplied from the station; and by the temporary load factor for any period, I mean the ratio of the average current during that period to the maximum current supplied during that period. If we adopt these three, I think they will be sufficient for all our purposes.

Now we come to the question of high pressure supply. It was perfectly obvious, from the earliest attempts at distribution, that we should lose very considerably if we tried to extend low pressure to any great distances, and the obvious remedy for the difficulty lay in using high pressure, which involves smaller wires, at any rate. The old attempts that were made were of two kinds. The first attempt was by means of storage batteries; and in my previous Cantor Lectures I was able to give you an account of a great attempt that had been made to introduce such a system at Colchester. The scheme died from various causes, among others, that the batteries which were employed were not thoroughly reliable. An exactly similar scheme has since been worked out in Chelsea, by the engineers who superintended the Colchester system; we have there an example of storage batteries, put into sub-stations, which are charged all in series by high tension mains, and which discharge into the houses by independent low pressure mains. That system is one which we can see now, as the result of some time of working, is satisfactory in many ways, the only serious objection being probably its cost. That is the only case of that sort which has been before us, and is one which interests us very much, as being a development we would wish to see thoroughly successful. The other attempts directed towards a system of parallel-series made in previous days were all distribution, as we have called it. The lamps and mains were divided into groups, the lamps of each group being put in parallel, and the successive groups put in series—*e.g.*, it would be possible to have a dynamo working at 400 volts, with five main wires in the distribution network, the lamps being placed between the first and the second, the second and the third, and the third and the fourth. There would be thus four groups of lamps, which would be in series with each other, each group only taking its hundred volts, while the dynamo would be giving 400 volts, and we should be thus able to go four times the distance that we should with the ordinary two-wire system, or to twice the distance that we could with a three-wire system of 200 volts. This system has been adopted in several cases abroad; even at the time of my previous lectures it had been used for some time in Hungary, at Temesvar. It has been since then more extensively introduced by one or two central stations; the most notable one being the Secteur Clichy in Paris. The difficulty with this system of distribution lies in the fact that when at any time of the day the number of lamps upon the different groups is not equal, the groups which have the fewest lamps have the highest pressure working on them and the lamps are too bright, while those groups which have the greatest number of lamps have the lower pressure and are too dim. Various attempts have been made to get over this trouble. I showed you in my previous Cantor Lectures an arrangement which I myself had tried to elaborate, of

an automatic switching of the lamps from one set of mains to the other, but I think it is too complicated and not likely to succeed. Another plan occurred to me at the time, but the difficulties in the way of introducing it seemed so great that I did not mention it; this has been introduced in the Secteur Clichy, Paris. There is introduced at the different parts of the network what is called a compensator, which consists of four different dynamos all on the same shaft, and each dynamo is connected on one of the four groups. Suppose there is one circuit receiving too much pressure because there are too few lamps, then the pressure on the dynamo corresponding to that group is greater than the other four dynamos, and it will therefore act as a motor and be driven at greater speed than if it was quite out of the circuit. Being driven at greater speed, it raises the pressure in all the other different circuits, and thus in the circuits in the groups which have least pressure, the corresponding dynamos are acting as dynamos generating electricity, and in the groups where the lamps are fewest, they are acting as motors absorbing current and giving power to the dynamos. This is not satisfactory, the compensator requires to be continually at work, and the experience of the directors of the Secteur Clichy is that about twelve horse-power is being wasted in friction of the machine, and the consequence is, it is a very wasteful system to introduce. Even though the machines are extremely perfect and require very little attention, still they need lubrication; the brushes need some attention; so combining the attention required and the waste there is in the friction of the machine, the system has not been approved, and is going to be abandoned. The alternative to which they have been driven is to use batteries of accumulators to act as compensators, put in at different parts of the network of mains—a series of batteries, say 50 cells each, between each of the pairs of mains; that is to say, in parallel with each group of lamps. These batteries will maintain the pressure, and if there are too few lamps on one group, the current will pass through the battery and will be charging it up, and the battery will act as a regulator. They behave extremely well, but batteries are, of course, an expensive item. You will notice that this five-wire system—which would be more satisfactory and more economical—is very similar to Hopkinson's many wire system—an extension of his three-wire system, patented by Hopkinson and Edison simultaneously. The difference is that in Hopkinson's there is not a single dynamo of 400 volts, but four dynamos of 100 volts each, and they are put upon the separate groups. At the moment when the number of lamps on each group is the same, there will be no current passing through the intermediate wires, the four dynamos will be generating their 400 volts, and the current will be going in at one extreme wire and coming out at the other. When the lamps are used more on one group than another, then the intermediate wire will carry current, and one dynamo will be doing more work than another. I cannot conceive how they could have introduced in Paris an unnecessary difficulty by putting in one dynamo of 400 volts instead of four, which obviates very much the difficulties. Coming down to other high pressure systems, the most important, and the one which has received the most development, is the alternate current transforming system. The convenience of this is enormous; we are able to send an alternating current through an extremely fine wire to a great distance — a main one-twentieth part of the section will carry current supplying the same energy as in the low tension. Of course it is dangerous to bring the high tension into our houses; but the transformer gives us the utmost facility, by the most beautiful contrivance, of transforming down and producing low pressure. By passing the current through one set of coils in the transformer, we do, by alternately magnetising and demagnetising the core, induce in the secondary coil—totally distinct from the primary—currents which are of low tension. This is of the utmost importance, because, in a properly constructed transformer, it is possible to ensure absolute immunity from danger, and from the high pressure entering the house. I regret that that is not always done in practice; inefficient transformers have been introduced, but there is no excuse for bad work in that way. The alternating current lends itself to distribution in another way, and this is a point which has not been sufficiently attended to in the past. The method which I have suggested is about to be adopted in the lighting of the city of London, and I think, when once it has been introduced there, it will be generally adopted in other cases.

You will remember, when I was speaking about feeders and low pressure systems, I showed you that there was some difficulty in regulating the pressure in different feeders. There is not the slightest difficulty in this way with alternating currents. This

can be done simply by the introduction of what is called a choking coil—coils of wire, in the centre of which we can introduce iron wire. By this means we are able to reduce the electromotive force which is acting upon a feeder, without consuming energy, at the same time; and the distance to which we introduce the iron into the centre of the coil gives us the means by which we can regulate the E.M.F. on that feeder. We thus have the most perfect way of regulating the pressure in the different feeders. Another method is equally applicable, and that is to pass the current through a transformer in the central station, and take off the current from the whole of the secondary coil in the transformer, or rather less. We may switch on to different parts of the secondary coil, and thus, by adjustment, can take off current at 100 volts, and at different voltages. These two methods will, in the future, be of the utmost importance in electrical distribution by means of the alternating current.

The alternating current has been objected to, on a great many different occasions, by those who are either interested in supporting low tension for some reason, or who do not fully appreciate the merits and advantages of the alternating current. There have been certain disadvantages connected with it, which we must look to; and if we hope for the alternating current to survive as the best system, we shall wish to see these difficulties removed. The first important difficulty we need pay attention to is, that hitherto it has not been good for driving motors. This is not so serious a difficulty as it looks at first sight. The experience gained where motors have been put on lighting circuits has not always been favourable to that arrangement, and in many central stations it is found desirable to have separate machinery and separate distribution mains for the motor circuits. If the motors are not under the same conditions as the lights, and are doing at all heavy work, or are put suddenly on to a very large amount of work for a short time, such as lathes, &c., a strain is put on the electrical supply in the immediate neighbourhood, and the lamps in the vicinity become dim. In a motor circuit, the regulation of pressure to a very great nicety is not of such great importance, but in lighting circuits the regulation is of the utmost importance; therefore it is not desirable that they should be put on the same circuit. One of the chief reasons alleged for putting motors on the lighting circuit was that the load factor would be improved. This is not the case, however, as the two overlap at the busy time, the maximum amount of light being required at the same time that current is required for the motors. I believe that in the future developments of central station distribution by means of alternating current we shall have got over these difficulties entirely. The other difficulty which really needs to be overcome relates to electro-chemical operations; for these the alternate current is not very suitable. Of course we cannot charge storage batteries, nor can we use the alternating current for electro-deposition. But current for electro-deposition is not generally let out from a central station; if it were a good plan to do so we might see a solution to the load factor problem by letting out current at cheap rates; as a matter of fact, for electro-deposition works it is cheaper to generate electricity direct than to take it from a supply company. As to storage batteries, it is very convenient to be able to charge storage batteries, but so long as our station is so managed that we do not require any reserve power, the necessity for storage batteries diminishes; and I must say, as the result of practical experience in the past, we are improving every year in the certainty of our supply of electricity, so that at the present moment there is really only an infinitesimal number of stations being called upon to supply electricity from storage batteries, and every year is diminishing the possibility of such a thing. I must say that such a supply is an advantage not to be overlooked in a well-regulated central station.

Now, I have said there will be some considerable changes in our methods of distribution of electricity by means of the alternating current. The greatest alteration which I expect will occur lies in the fact that it will be found most satisfactory from many points of view to introduce sub-stations. Up to the present it has been the custom, when using alternating currents, to put a transformer in the house of each consumer. It is in the first place somewhat costly to make separate transformers. In this, as in all other cases, if you make up a thousand horse-power in small units you require a very great deal more material and labour than when you make up the same in larger units. It is also inconvenient to put transformers in the houses for another reason, namely, that it is very much

more difficult to regulate the pressure so as to keep it perfectly constant at all hours, because, in addition to the changes in the pressure owing to the distribution, as in the low tension distribution, we have an actual loss in the transformer, and though a great part of this loss is a perfectly constant fall of pressure, and therefore does not affect the distribution problem, still there is a certain amount which is variable with the load; therefore we are introducing by this system an extra difficulty in regulating pressure. If we introduce sub-stations from whence the low tension is distributed, the pressure regulation can be done by attendants, provided always that we make them sufficiently large to make it worth while to employ attendants. There seems not the slightest doubt that we shall be able to adjust this in another manner, by making the transformers self-regulating to a certain degree, so that it will be possible to place these large sub-station transformers in underground vaults, say, in places where they only require very occasional inspection, and where they do not require to have continual attendance. There are several inventions which have been made in this direction, and I had hoped to show you some which have been introduced by Mr. Ferranti; and he himself would have been most willing, but unfortunately, as you know, there are some troubles connected with foreign patents, and the possibility of too much being divulged prevents me from showing this apparatus. You can perfectly easily see that it is possible to arrange some sort of automatic switch, so that when the demand for current increases, an additional transformer will be switched into the circuit, and when the current falls off, this switch will act in the opposite direction and put in a smaller transformer. It is also possible to wind our transformers, both primary and secondary, with more than one wire, and to have an automatic arrangement by which these coils shall be put in series or parallel, primary and secondary simultaneously, according to the different demands for current; that also will get over our difficulty. The effect of such changes will be to make the transformers work at their economical load. There is always a loss in a transformer due to hysteresis, and that loss is pretty constant whatever the demand for current may be. Now, by proportioning the size of our transformer to the load required, we are able to make the hysteresis loss a small proportion of the total current required to keep the transformer working at its efficient load.

At the present time, with a transformer in every house, transformers are working in a very inefficient manner during the greater part of the time, both when the load is light, and during the daytime, when no secondary current is being taken at all. These transformers must always be supplied with current, and even during the daytime consume an appreciable amount of energy—that used in overcoming the hysteresis of all the transformers over the whole town. But with our sub-stations supplying secondary low tension to the mains, we shall have only a very small number of transformers at work during the hours of light load; and the consequence will be, that each transformer will be working in an efficient manner during the whole 24 hours. I think we may safely look for an average efficiency of 90 per cent. during the whole of the 24 hours. I may say the feeling at the present time is very general among engineers that sub-stations ought to be introduced, instead of having transformers in every house.

If we are to introduce these sub-stations, it becomes necessary to review the whole system of distribution, and consider whether we are working in the right direction. There is one point requiring radical modification, *i.e.*, the frequency of alternations used in connection with our distribution. When the pioneers in this line started work it was of course looked upon as a great feat to get nearly the whole of the energy transformed and supplied in the secondary circuit; and it was a great feat to do this by means of cheap apparatus. It was impossible to do this cheaply and economically, unless we used very small transformers; and the only way in which we could use very small transformers, with high pressures of 1,000 volts, was by having rapid alternations, and consequently the pioneers used dynamos which gave very rapid alternations and a very small transformer. The result is, that you get a very considerable consumption of energy due to the hysteresis of this transformer.

Now when we come to use sub-stations with very large machinery, the economy which is to be gained by using high frequency is not nearly so large, not nearly so well worth considering, as it is when we are dealing with scattered lighting, and able to put transformers more economically in every house. For this reason then, I think it would be desirable to reduce the frequency of our alter-

nations as low as the frequency of the alternations in an ordinary continuous current dynamo armature. That is to say, reduce from 130 and 80 periods per second down to something like 5 or 10 periods per second. There are other reasons why we should use low frequencies. When we have secondary mains of that large section of copper used in our low pressure systems, it is only with difficulty that we can force a current of high frequency through it. High frequency has a remarkable effect on the conducting qualities of large conductors. The whole of the current is forced towards the outside of the conductor and makes the inside of the conductor almost useless as a means of carrying the current. It is only by diminishing the frequency of our alternations that we shall be able to get over this very serious trouble, which will attack us as soon as we have low tension mains carrying alternate currents. There is another advantage in using low frequency currents, and that is, the problem of electro-motors is immediately solved. It has been a wonder to many why we could not use continuous current motors with the alternating current, if the field magnets were made of laminated iron. It was said that a current in the one direction drives the motor in the one way, and if we reverse the direction of the current, it still goes on in the same way. Why should not this happen with an alternating current? So it would, but the employment of an alternating current to magnetise the field magnets of these motors involves an enormous counter E.M.F. set up in the coils round the field magnets, as the effect of what is known as self-induction; the consequence is that a great proportion of the volts which we supply to the motor is taken up in magnetising the field magnets. I have calculated out the particular case of a 10 horse-power motor working at 100 volts, and I find that though the field magnets be laminated in the best possible way, this motor, when worked by an alternating current, would require 99 volts in addition to the 100 volts actually needed when worked with a continuous current—practically 100 extra for exciting the field magnets. When that motor is used with a continuous current, only $\frac{3}{4}$ volt is required for magnetising the field magnets, so that you would have to work at 200 volts to supply the motor with an effective E.M.F. of 100 volts, and yet at the present moment motors of that character are being used largely in America on lighting circuits, for some purposes where the power used is small, so that an output of 30 or 40 per cent. of what might otherwise be obtained is ample for the purpose. I have calculated that if you were to reduce the frequency to five periods per second, the volts required in that case for exciting the field magnets would be 6 instead of $\frac{3}{4}$ volt. We should thus be diminishing the output of the motor down to 90 per cent., which is not a serious thing, and be making the use of such a kind of motor practicable. We know perfectly well that alternating current motors are being developed by other means, and that some of them are far superior in practical working to any of the continuous current motors; and, consequently, the direction in which this part of the subject will be extended is almost certainly in the development of these new types of motors, which have attracted so much attention elsewhere. Even for that class of motor too, there is no advantage in having high frequency, and it will be a distinct gain to have low frequency. Low frequency will also enable us to introduce a commutator in such a way as to convert alternating current into continuous, and that will enable us to charge storage batteries. At the present time the only way of doing this with alternating current is to employ an alternating current motor, and cause it to drive a continuous current dynamo machine. By that means we are able to charge storage batteries; but by introducing low frequency the advantages are so great that I think it is most desirable, when we are considering the question of using substations with large transformers supplying the secondary mains, that we should also consider the other alternative of using low frequency, and a commutator to convert the alternating into a continuous current. The only reason why we use high frequency is the large number of transformers; it economises their construction, and we are able to have a cheaper transformer; but you will see that that *desideratum* is diminished when we come to the sub-station method of distribution.

Other systems of establishing high tension have been proposed, the most important that has received attention being the continuous current transforming system, which consists in sending high tension continuous current from a central station to a distant substation, where the current is received and passed through a motor, which serves then to drive a continuous current dynamo of low pressure. That dynamo then serves as a source of energy to the neighbourhood around, supplying the mains in its immediate neigh-

bourhood. We can have several of these sub-stations, so that from one central station we are able to distribute our power in the form of high-pressure electricity to several distant points, and then to produce low-pressure electricity and distribute through our mains. These combination machines, of motor and dynamo combined, can be made of a very high degree of efficiency owing to a remarkable fact. The efficiency of a dynamo or motor is impaired by the reactions produced by the currents in the armature, and these reactions, in the case of dynamo and motor, are in opposite directions. If now we wind a high tension winding on an armature to serve as that of a motor, and on the same armature we wind a low tension winding which is to act as that of the generator for the low-pressure supply, and put a separate commutator and a separate pair of brushes to each of these windings, we have the same machine acting as a motor and as a dynamo, and we have an absence of those armature reactions which would be produced either by the motor winding or by the dynamo winding alone, because they are produced in opposite directions by the two windings when we use one as a motor and the other as a dynamo, consequently we have an apparatus which is extremely efficient and useful.

We must consider the fact that, in working this way, we are conveying our power from our central station to the sub-stations by means of high-pressure electricity; and we are committing ourselves to the statement that high-pressure electricity is the most economical means by which we can transmit power from one place to another. There are several ways in which we can carry power from a central station to different parts of a town. We can do it by passing air compressed at a central station through pipes to the different sub-stations, there using it in engines, which may be ordinary steam-engines, to drive our dynamos. Or, we may do it by means of water which is kept under pressure by pumping it into hydraulic accumulators at a central station. From this central station the high-pressure water may similarly be led through mains in the town, and be utilised in water motors for driving the electrical machinery at the sub-stations. These are two ways, besides the electrical way, in which power may be given to the sub-stations from the central source, and we have to consider which of these three is the most economical. The compressed-air method is being largely used at Birmingham; it is also being used for electric lighting in Paris on the Popp system. I do not say that at the present moment the results have been altogether economical, but I do say that the system of transmitting our power to sub-stations by compressed air deserves far more serious attention than has been generally accorded to it. I have heard people who were in ignorance of the methods which can be used for supplying compressed air, or who have only had experience with very defective apparatus for this purpose, speak of the mere 20 or 30 per cent. efficiency obtainable; this is utterly erroneous. The efficiency you can get is very good indeed, and the difficulty lies not so much in that as in the large space taken up in the streets by the pipes to carry the compressed air. The same remarks apply to water-power. High-pressure water is now being distributed through London from the large central stations of the Hydraulic Power Company. That water is used chiefly for working lifts or elevators; it may be used for other purposes. Here, also, the economy is good. Here, again, the difficulty is a 6-inch main which is being used. The total power which can be supplied through such a size of main at the pressure of 700 lbs. is something like 100 horse-power. So that, when we come to transmit large powers, the space which would be occupied by the mains would be too large to allow of the system being really practicable in most cases. There might be cases in outlying towns—in parts of London even—where the roadway is not filled up with pipes, where it might be desirable to introduce compressed air or hydraulic power. But probably these cases are very few; and certainly in busy parts, like the city of London, or the greater number of the streets in London, it would be too expensive to proceed in this way. So that, in all probability, the high-pressure electrical system is the best for supplying sub-stations; but I beg electrical engineers not to cast aside, as utterly useless, the other means of supplying power from central stations, which may, in some cases, be useful. There is still another way, and that is by the distribution of gas: either the ordinary illuminating gas, or gas specially prepared for heating purposes. Of the latter kind, the best known is the Dowson gas, which can be produced extremely economically—at about 10d. per 1,000 feet. The question is, simply, Is it ever economical to introduce gas-engines in sub-stations, instead of generating power by steam-engines? I have no hesitation in saying that it is in very many cases economical. Gas-engines have increased in use in the last few

years; the sizes of gas-engines have also been increased. Hitherto gas-engines have not been made very large, solely because the purposes for which they have been required have generally been those requiring small amounts of power; and people have been doubtful of their applicability to purposes requiring large power. The largest gas-engines indicate 170 horse-power with ordinary gas, or about 160 with Dowson gas. Such gas-engines are in use in London, and can be seen at work at any time; there are also 98 horse-power engines working at Portsmouth for generating electricity. The floor space taken up is 14 square feet, therefore the space is not large compared with steam. It would be perfectly easy to make larger ones if they were wanted, but I believe that, for such sub-stations as those in which they would be likely to be used, 170 horse-power is as large a size as it would be desirable to introduce; and we should, therefore, be simply using gas-engines on the market at the present moment. It is asserted that only 16 cubic feet of gas per horse-power hour indicated is used, and, therefore, even allowing a slight margin for the sanguineness of the manufacturers, we should reduce the cost of power to a very moderate figure, especially in places where gas is very cheap. When we look at this question of using gas-engines in its bearing on the load curves I have been speaking of, you will see the enormous gain gas-engines could effect. With gas-engines, you do not require to be firing up boilers long beforehand for a few hours' work; your gas is always ready, and you can start at the time you have to supply power, without having gone to any waste beforehand in getting your plant into working order, as with steam plant. A large proportion of the 9 or 10 or 15 pounds of coal to the electrical unit needed with steam plant is consumed in heating up the boilers preparatory to starting work; and this means considerable expense, which would not be incurred if gas-engines were used. I am sure the question will attract the attention of engineers, and that in designing central stations in future, this plan will not be lost sight of.

I will now conclude with referring shortly to some of the systems adopted for laying conductors underground, and will describe to you an ingenious automatic safety device of Mr. Ferranti's, which is appropriate to this lecture. I need hardly take up time with describing different kinds of cable used. We have cables insulated with vulcanised india-rubber, okonite, various bituminous compounds, and air. Some people have used lead-covered cables, while in other cases the conductors are left bare. I pointed out, a few years ago, some serious defects which had occurred in the lead-covered cables employed in Berlin and Rome, due to faults in the manufacture, and want of care in laying. Great improvements have, however, been made since then. I also described, at the meeting of the British Association in Manchester, in 1887, a system of mains which is exceedingly simple. I use cast-iron pipes, and run bare copper tubes through them. The copper tubes, which are supported on porcelain insulators (Fig. 1, p. 881), may be first used as the conductors alone, and when the demand increases, bare wires can be drawn through the tubes. In the figure, which is more or less diagrammatic, the method of making a house connection is shown, iron tubes being tapped into the side of the pipe, through which the house mains are led and soldered to the outside of the copper tubes only, the inner wire-conductors being left untouched.

Fig. 2 (p. 881) shows a Crompton conduit formed of concrete, in which bare copper mains rest on glass insulators supported on oak bars. At the extreme left is shown the arrangement by which the copper strips are kept from sagging down between the insulators. The copper strips are passed through the bridge piece, which is insulated from the cross-bars by glass insulators also, and when pulled taut are nipped by the set-screws, one of which is shown in the sketch, and thereby kept in position.

In Fig. 3 (p. 882) is shown a section of the conduit used by the St. James's and Pall-mall Company. This consists of a cast-iron trough with cover, the two being joined by a red-lead joint, and bolted together. Bare copper strips are supported edgeways on porcelain insulators, bridging over the bottom of the conduit to allow of free drainage, and are held in place with wooden wedges; between the insulators porcelain distance pieces rest on the copper strips to keep them apart, as shown in the figure.

One of the well-known Callender bitumen concrete casings is represented in Fig. 4 (p. 882), through which insulated cables are drawn. An objection to this conduit is its perviousness to water. In tests that I have made, a block with four ducts, weighing 20 lbs. 8 oz., absorbed 4 oz. of water during an immersion of 46 hours. Another piece, with two ducts, weighing 6 lbs.

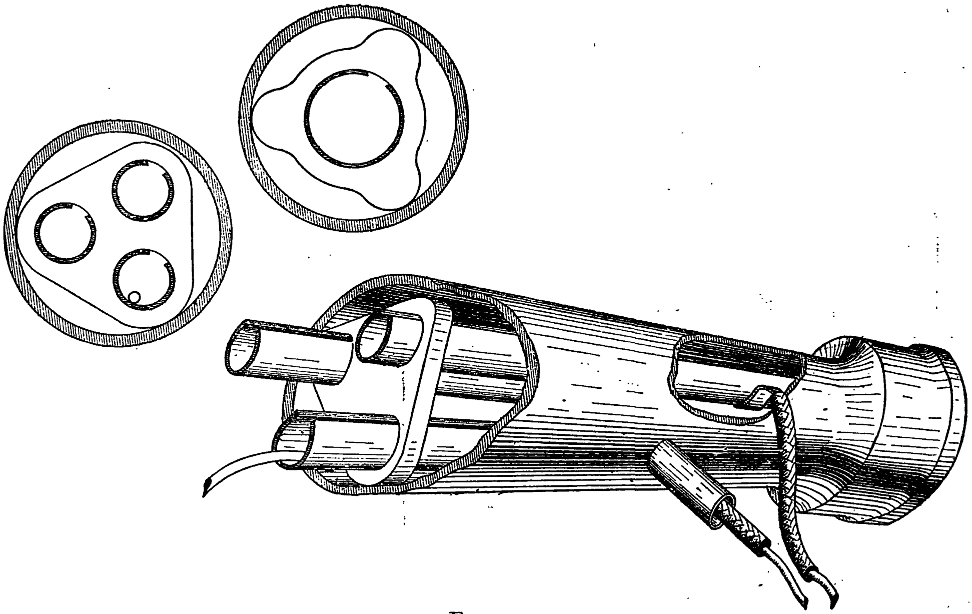

FIG. 1.

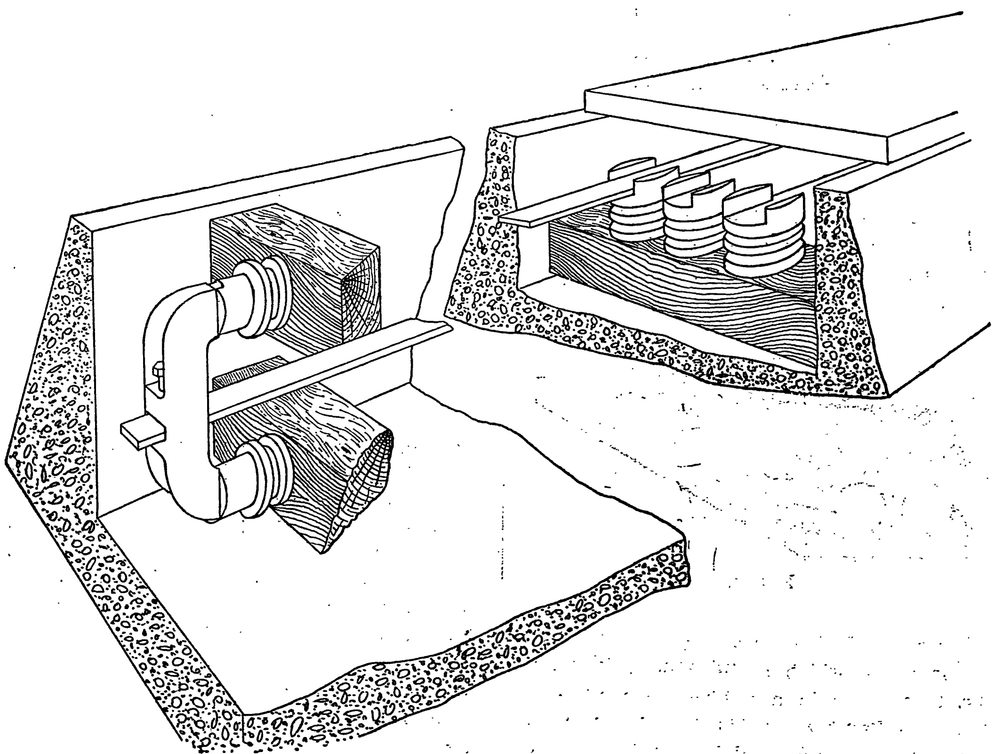

FIG. 2.

13 oz., absorbed 1 oz. in 46 hours, the water being put in the ducts, which were plugged up at one end. In this latter piece a pin-hole was found leading from one of the ducts to the outside, through which the water leaked.

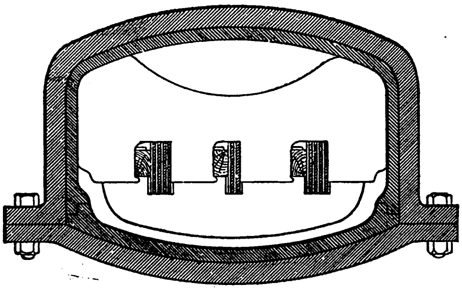

FIG. 3.

Lastly, in Fig. 5, we have the Macdonald conduit. This is made of creosoted wood, and consists of three or more pieces, joined by tongues running the whole length of the conduit. The labour of laying this conduit is

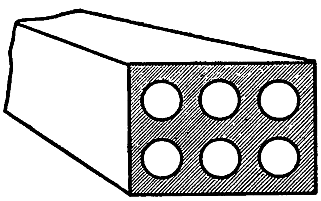

FIG. 4.

small, and the number of ducts can be increased by merely adding centre pieces, the pieces being laid so as to overlap at their ends as shown, thereby forming a compact whole.

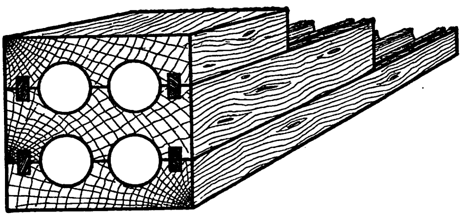

FIG. 5.

The safety device for alternating circuits I mentioned, of which a diagram is shown in Fig. 6, consists in a means for cutting off the supply to a house when there is a leakage on any circuit, or a breakdown of the insulation of the house transformer. A and B are the primary circuits, and C, D the secondary, of two small but similar transformers, the primaries being in series and placed as a shunt across the house mains, the secondaries also being in series but forming part of a distinct circuit, in which is included a fuse as shown, on which is suspended a plug which, if allowed to fall, short-circuits the house mains between the points F and G. The primaries and secondaries of the two small transformers are connected up so that the E.M.F.'s of the latter oppose each other, and, being equal

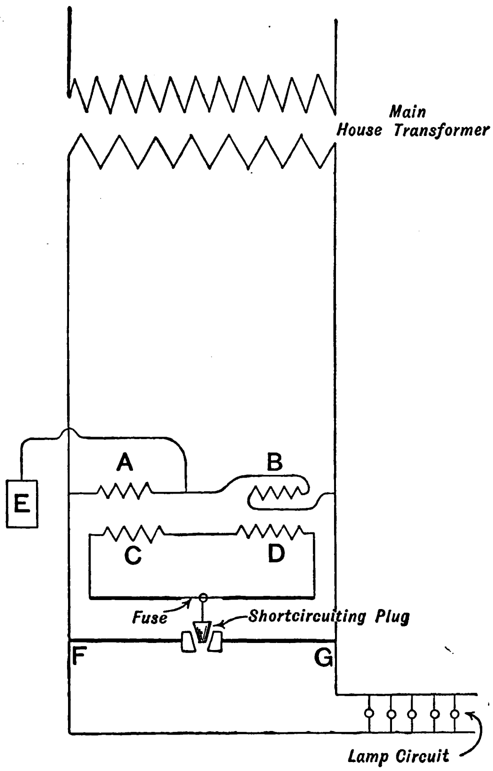

FIG. 6.

in magnitude in the normal state of working, consequently produce no current in the fuse circuit. The junction of the primaries is at all times connected to earth. Now, suppose a leakage occurs on the lower wire of the lamp circuit. This will upset the balance of the two transformers, by reducing the current passing through A, consequently the E.M.F.'s in the secondary circuits of the transformers will not now be equal, but that in D will overcome that in C, and a current will pass through the fuse and blow it out, allowing the plug to fall and short-circuit the house mains, the

result being that the main fuse (not shown) will be blown out and the supply to the house be cut off. The same thing will result if the pressure rises at either terminal of the secondary of the main transformer, owing, say, to a leakage from the primary to the secondary. In the actual apparatus there is a third block, connected to earth, that the short-circuiting plug makes contact with when it falls, thereby putting the house circuits to earth effectually, and minimising all risk from shocks.

Miscellaneous.

THE CHICAGO EXHIBITION.

Reuter's agent at Chicago sent the following information to the papers this week about the recent appropriation voted by Congress for the purpose of the Exhibition:—

Although the appropriation made by Congress for the World's Fair was reduced during the debate in the House of Representatives from £1,000,000 sterling (5,000,000 dols.), to £500,000 (2,500,000 dols.), the result will, it is believed, be extremely satisfactory to the managers of the Exhibition. The money was granted in the form of 5,000,000 special souvenir silver coins, of the weight, fineness, and value of the regular silver half dollars in current use. As soon as it became known that the souvenir coins were to be issued to the Fair officials from the United States Mint at Philadelphia, there was an immediate demand for them from all parts of the country.

It at once became apparent that the coins could be disposed of by the Exposition at a large premium. The editor of a leading New York newspaper offered 100 per cent. premium for 10,000 coins; merchants and bankers made similar offers, and during the five days succeeding the passing of the Bill, tenders were received for 600,000 of the coins at 100 per cent. premium. A syndicate of bankers in the West offered to take the entire issue at 60 per cent. Fabulous offers have also been made for the first souvenir coin struck at the Mint. A Chicago newspaper started the bidding at £25, but several wealthy men in Chicago have expressed their intention of securing this coin if it costs £200. It is probable that the coin will be sold at public auction in Chicago, a certificate from the Director of the Mint going with it to guarantee that it is the only genuine first souvenir coin. It is probable that all the coins will be sold by the World's Fair Management at 100 per cent. premium, and that the Exposition will be enriched to the extent of £1,000,000 by the national appropriation.

*THE UTILISATION OF NIAGARA.**

Few persons can have seen Niagara Falls without reflecting on the enormous energy which is there continuously expended, and for any useful purpose wasted. The exceptional constancy of the volume of flow, the invariability of the levels, the depth of the plunge over the escarpment, the solid character of the rocks, all mark out Niagara as an ideally perfect water-power station, while, on the other hand, the remarkable facilities of transport, both by steam navigation on the lakes and by four systems of railway, afford commercial advantages of the highest importance. From a catchment basin of 240,000 square miles, an area greater than that of France, a volume of water amounting to 265,000 cubic feet per second descends from Lake Erie to Lake Ontario, a vertical distance of 326 feet, in 37½ miles.

Supposing the whole stream could be utilised, it would supply 7,000,000 horse-power. This is more than double the total steam and water power at present employed in manufacturing industry in the United States.

Immediately below the Falls the river bends at right angles, and flows through a narrow gorge. The town of Niagara Falls on the American side occupies the table-land in this angle.

The earliest traders who settled near the Falls erected stream mills in the Upper River in 1725, for preparing timber. Later, the Porter family erected factories on the islands in the rapids above the Falls. It was not, however, till about thirty years ago that any systematic attempt was made to utilise part of the water-power of the Falls. Then a canal was constructed from Fort Day, about three-quarters of a mile above the Falls, to a forebay or head-race along the cliff overlooking the lower river. In 1874 the Cataract Mill was established, taking power from this canal, and other mills were gradually erected till about 6,000 horse-power was utilised. These mills have been exceedingly prosperous, but since the growth of a feeling against the disfigurement of the Falls, it has become impossible to extend works of the same kind.

The idea of a method of utilising the Falls, capable of greater development, and free from the objections to the hydraulic canal with mills discharging tail water on the face of the cliff, is due to the late Mr. Thomas Evershed, Division Engineer of the New York State Canals. He proposed to construct head-race canals on unoccupied land some two miles above the Falls. From these the water was to fall through vertical turbine pits into tail-race tunnels, converging into a great main tunnel, discharging into the lower river. Apart from an inappreciable diminution of the volume of flow over the Falls, this plan avoids any disfigurement of the scenery near the

* Extracted from the opening address of the President Professor W. Cawthorne Unwin, F.R.S., to the Mechanical Science Section of the British Association.

Falls, and permits a head of nearly 200 feet to be made available. It is, however, essential to such a plan that work should be undertaken on a very large scale. In 1886, the Niagara Falls Company was incorporated, and obtained options over a considerable area of land, extending from Port Day for two miles along the Niagara River. In 1889, the Cataract Construction Company was formed to mature and carry out the constructional works required.

The present plans contemplate the utilisation of 100,000 effective horse-power. The principal work of construction is a great tunnel 7,250 feet long, which is to form a tail-race to the turbines, starting from land belonging to the company and discharging into the lower river. The tunnel is 19 feet by 21 feet, or 386 square feet in area, inside a brickwork lining 16 inches thick.

The base of the tunnel is 205 feet below the sill of the head gate, and permits a fall of 140 to be rendered available at the turbines. The brickwork of the tunnel is lined for 200 feet from the mouth with cast-iron plates.

The tunnel has been excavated with remarkable rapidity with the aid of drills worked by compressed air.

The main head-race, about 200 feet wide, will run for about 5,000 feet parallel with the river, having entrances from the river at both ends. Near the lower reach the Soo Paper Company is already arranging to utilise 6,000 horse-power, discharging the water from the turbines through a lateral tunnel into the main tunnel. Near this lower reach will also be placed two principal power stations, from which will be distributed, either electrically or otherwise in ways not yet fully determined. The first turbines to be erected in these power stations will be twin turbines of the outward flow type of 5,000 effective horse-power. These turbines have a vertical shaft for driving dynamos or other machinery placed above ground.

According to Mr. Evershed's original plans, it was intended to distribute water by surface canals to different power users, each of whom would sink his own turbine pits, connected below by lateral tunnels to the main discharge tunnel. Some of the power at Niagara will undoubtedly be used in this way, and in the case of industries requiring a large amount of power, it will be economical to purchase a site and water rights.

Such a plan is, however, not adapted to smaller factories. Obviously for them it would be more economical to develop the power in one or more central stations by turbines of large size under common management. Further, once given the means of distributing power instead of water, an important extension of the project becomes possible.

Besides supplying power to industries which may locate themselves at Niagara, the power may be transmitted to the existing factories in Buffalo and Tonawanda.

Arrangements are already proceeding to transmit 3,000 horse-power to Buffalo, a distance of 18 miles, to work an electric lighting station.

In 1890, Mr. Adams, the President of the Niagara Construction Company, visited Europe to examine systems of power distribution. It was in consequence of this visit that the important modifications of the plans of the company involved in the substitution, to a large extent, of a system of power distribution for a system of water distribution came to be adopted. The American engineers were anxious to obtain the best European advice as to the methods best suited to the local conditions. A commission was formed, consisting of Lord Kelvin, Dr. Coleman Sellers, Professor Mascart, and Colonel Turrettini, and an invitation was given to engineers and engineering firms in Europe and America to send in competitive projects for the utilisation of the power at Niagara and its distribution to different consumers at Niagara and in Buffalo by electrical or other means. Many of the plans sent in were worked out with great care and completeness. As to the hydraulic parts of the projects, there was some approach to general consent as to the arrangements to be adopted, but as to the methods of distributing the power there was an extraordinary diversity.

Generally the Commission reported in favour of electrical distribution, with perhaps a partial use of compressed air as an auxiliary method.

Generally also they reported in favour of methods of distribution by continuous currents in preference to alternating currents. Since the date at which the Commission reported, the Frankfort-Lauffen experiment has been made, and in the opinion of some electrical engineers a distinct advance has been achieved in the use of alternating currents at high potential.

The company has not yet decided to adopt any plan for the central stations except in a tentative way. One or more turbines of 5,000 horse-power are to be erected, and probably at first this power will be distributed to Buffalo by an alternating current system.

The cost of a steam horse-power at Buffalo is reckoned at $35 per annum. I believe the company will be able to deliver power at from $10 for large amounts and a greater price for small amounts, this price being reckoned for twenty-four hour days.

The new industry of electric lighting has made necessary the provision of large amounts of motive power. Electric traction similarly depends on the supply of motive power. New chemical and metallurgical processes are being introduced which entirely depend for their commercial success on the supply of motive power at a low price.

Niagara is likely to become not only a seat of large manufacturing operations of familiar types, but also the home of important new industries.

Chicago Exhibition, 1893.

MEETING OF THE ROYAL COMMISSION.

A meeting of the Royal Commission was held on Tuesday, August 30th. Present: Sir Richard Webster, Q.C., M.P., in the chair; Sir Frederick Abel, K.C.B., D.C.L., D.Sc., F.R.S., William Anderson, D.C.L., F.R.S., Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D., Sir Frederick Bramwell, Bart., D.C.L., F.R.S., Alfred Carpmael, Sir Henry Doulton, James Dredge, Sir Douglas Galton, K.C.B., D.C.L., F.R.S, Walter H. Harris, Charles Malcolm Kennedy, C.B., John Biddulph Martin, John O'Connor, with Sir Henry Trueman Wood, Secretary.

FOREIGN LABOUR.

The following joint resolution has passed the Senate and the House of Representatives of the United States. Its object is to authorise foreign exhibitors at the World's Columbian Exposition to bring in foreign labourers from their respective countries for the purpose of preparing and making their exhibits:—

"[Public Resolution—No. 30.]

"Whereas, under and in pursuance of the Act approved April 25th, anno Domini, 1890, the President of the United States has invited the Governments and citizens of foreign nations to participate in the International Exhibition authorised by the Act above recited; and

"Whereas the invitations so extended have been accepted by the several nations, and space for installing foreign exhibits has been applied for and duly apportioned, and concessions and privileges granted by the Exposition management to the citizens and subjects of foreign nations; and

"Whereas, for the purpose of securing the production upon the Exposition grounds of scenes illustrative of the architecture, dress, habits and modes of life, occupation, industries, means of locomotion and transportation, amusements, entertainments, and so forth, of the natives of foreign countries, it has been necessary for the World's Columbian Exposition to grant concessions and privileges to certain firms and corporations conceding the right to make such productions: Therefore,

"*Resolved by the Senate and House of Representatives of the United States of America in Congress assembled,* That the Act of Congress, approved February 26th, 1885, prohibiting the importation of foreigners under contract to perform labour, and the Acts of Congress prohibiting the coming of Chinese persons into the United States, and the Acts amendatory of these Acts, shall not be so construed, nor shall anything therein operate to prevent, hinder, or in anywise restrict any foreign exhibitor, representative, or citizen of a foreign nation, or the holder who is a citizen of a foreign nation, of any concession or privilege from the World's Columbian Exposition, from bringing into the United States, under contract, such mechanics, artisans, agents, or other *employés*, natives of their respective foreign countries, as they, or any of them, may deem necessary for the purpose of making preparation for installing or conducting any business authorised or permitted under, or by virtue of or pertaining to, any concession or privilege which may have been granted by the World's Columbian Exposition in connection with such Exposition: *Provided, however,* That no alien shall by virtue of this Act enter the United States under contract to perform labour except by express permission, naming such alien, of the Secretary of the Treasury; and any such alien who may remain in the United States for more than one year after the close of said Exposition shall thereafter be subject to all the processes and penalties applicable to aliens coming in violation of the alien contract labour laws aforesaid. —Approved, August 5th, 1892."

CANTOR LECTURES.

DEVELOPMENTS OF ELECTRICAL DISTRIBUTION.

By Prof. George Forbes, F.R.S.

Lecture III.—Delivered February 8, 1892.

It is almost impossible for any person at the present moment to give a lecture of any description dealing with electricity without making some allusion to the remarkable lectures that we have heard in the course of last week by Mr. Tesla; and the great bearing which those lectures have upon certain parts

of the subject upon which I am lecturing, leads one naturally to say a few words about the remarkable experiments and conclusions that have been before us. I saw in one of the technical journals, this last week, a remark that after the brilliant lecture of Wednesday evening the practical man would ask, "What is this to lead to?" Well, if the man who is in the habit of calling himself the "practical" man were to ask my advice, I should advise him to leave the experiments of Mr. Tesla quite alone. That man is hardly in the position of being able to appreciate, at their right value, the experiments which we saw. I trust that the time is passing by when those who have been in the habit of arrogating to themselves the title of "practical men" will continue to do so. Those men who apply that term to themselves do not realise the self-sufficiency which is shown by their assuming such a title. It is the highest praise which can be given to the greatest engineers to say that they are practical men. The man who assumes to himself the title "practical man" is generally the man who can use his hands but cannot use his head—the man who cannot apply theory or interpret a formula—the man who could attend to a well-known type of engine, but who would be incapable of appreciating what an enormous amount has been done in the ten years that such a thing as a Parsons' steam turbine has existed. Our great men do not speak of themselves in this boastful manner as being either practical men or geniuses. Our Watts, our Stevensons, our Rennies, our Bakers, do not boast that they are practical men. They are prepared to become so, but they would not make this boast. The man who largely assumes that title, then, I do not think will be able to appreciate the value of Mr. Tesla's work. But to engineers and natural philosophers it is full of importance. Engineers and natural philosophers both look to this work as telling them a deal which has been puzzling them in the past, and as holding out great hopes for the future. There is a great difference between the natural philosopher and the engineer. The natural philosopher claims only to be Nature's pupil. The engineer aims at being her master. In Mr. Tesla's experiments the engineer sees great difficulties which have been in his way completely explained and partially removed. He sees what has been troubling him with the use of alternating currents in mains, and how the current was being allowed to leak, and he sees how to remedy that defect. He sees things that have been puzzling him in the action of air condensers, by which the apparent capacity of the condenser is enormously greater than it ought to be if there were not going on that peculiar action of bombardment of the molecules, of which Mr. Tesla has spoken so much. The engineer also sees that Mr. Tesla has worked out a system of practical electric lighting producing a most pleasing light—more so than any which we have seen before, and by a means which is almost in a practical shape. The natural philosopher, on the other hand, sees explanations of a vast number of the experiments which have been puzzling him in the past, and sees new developments, new experimental investigations, which will lead to a better knowledge of the ultimate structure of matter. Mr. Tesla triumphs to-day as the natural philosopher. To-morrow he will triumph as the engineer.

The remarks which I have made upon this subject will lead you to see that I place very great importance on what Mr. Tesla has said about the construction of mains. We have long noticed that when an alternate current of high potential and frequency is passing through a wire, there is, in the dark, seen to be a light given off from the wire, especially near a telegraph post on which that wire is supported. This was particularly noticeable in the case of the experiments conducted at Frankfort in this last year, when a large amount of power was transmitted from a distance of 112 miles by a very high-tension alternating current. We were at a loss to completely understand what was the action which was going on there and how to overcome it. Mr. Tesla has given us the answer to both; but by going to these very high frequencies and very high voltages he has exaggerated all our difficulties, and thereby been able to see the meaning of them, and to give us the cure for them with the more moderate pressures and frequencies that we use in actual practice. And there is little doubt that he has given us the right explanation of the enormous value of oil as an insulator in all these cases. There cannot be too strongly impressed upon engineers the importance of oil insulation for cables which are carrying high-tension alternating currents over long distances. Those sub-station transformers which I was speaking about in my last lecture ought, in the future, to be altogether filled with oil. We had known the value of oil as an insulator before, but we had never realised the enormous importance of it; and now that we do realise the reason

why it is so important, it will be very much more largely used.

There are some other mains which I do not speak much about because they are so generally known. The Siemens concentric mains, of which I have specimens on the table, are extremely valuable for long feeders; but for distributing mains in the town, they have the serious disadvantage that a special kind of metal box has to be used to form a junction, when taking in the leads into any house that has a light. And the cost of this is so considerable, in order to make the joint perfect, that it seriously interferes with the economy of the mains. But, for feeders, these concentric mains are admirable. Also the fluid insulators which were introduced by Mr. Brooks—and which will be largely used, I trust, in the immediate future—are extremely valuable for the same purpose for alternating currents.

For the low-tension distributing mains, I draw attention once more to the type, of which I have a diagram here (see Fig. 1, Lecture II.), which I feel convinced is the most practical type which can be used for low-tension mains. The enormous value of this type of mains lies in this, that we can lay our mains over the whole district which is to be supplied at a very cheap rate at first, when the demand is small, and we are continually able to add to the size of the mains without the slightest difficulty. Then the whole thing is cheap to construct, and the attachments to houses are perfectly independent of the naked cables—the bare wire cables—which we draw through the copper tubes, and which we change for bigger ones, when the demand in the district increases.

I come now to the question of power as apart from light, and there are two totally distinct questions in connection with power furnished by electricity, the one referring to the *distribution* and the other to the *transmission* of the power, which are often intermingled. The engineer has to consider the two together very often, but they very often are completely separate and have different demands, and may necessitate the employment of different apparatus.

Let me just give an example or two to show how very greatly different is the case under different circumstances.

A great deal has been talked in the last few years about the employment of the Falls of Niagara for supplying power to a distance, it may be. It was originally suggested by Sir William Siemens and Sir William Thomson to carry the power from Niagara into New York; and later, more practical problems have been presented for carrying that power to Buffalo, a distance of thirty miles, and a manufacturing centre. In either of these cases the great problem is the transmission of the power. To distribute it through the town is not of such enormous importance. The best means which can be devised to carry the power from Niagara to Buffalo, and change it into power there, even though it be in the outskirts of the town, is the solution of a very great problem. But, on the other hand, take the case of a power-station situated in London—let us say in Clerkenwell, where there are an enormous number of small factories or small workshops which require power. They have steam-engines at the present moment doing a great deal of that work. Those steam-engines take up room which is valuable, and they are in the way, and so are the boilers. Again, these small engines are not economical. The consumption of coal is enormous compared with the power given off; and the demand for extra attendants for looking after the boiler and engines is a serious drawback in these small workshops. There could be no place more suitable for putting down a power-station than Clerkenwell, but there the demand is totally different to the above case. It is not simply a question of generating power in one station, and then supplying it continuously to the motors in the houses and keeping the motors always going. These motors in the workshops require to be stopped and started at frequent intervals; whereas in the transmission question we do not require to be always stopping the motors. We can be running them steadily all the time. This introduces a very great difficulty, because many motors which are most available to us are incapable of starting freely every few minutes, as when we require to start working a lathe or anything of that sort, and therefore for the distribution of power we must have special kinds of motors which are capable of starting frequently with the utmost ease.

Of course when we are transmitting power to a great distance it is perfectly obvious that we shall be obliged to use high pressures. If we do not use high pressures we shall be obliged to use large conductors, in order that we should not waste much energy on the road; and consequently, whatever system we are going to use—whether we are using continuous currents or whether we are using alternating currents—we must be dealing with high pressures. Every

special case needs to be calculated out on its merits as to the pressure which will be required and the size of the wires which we shall have to use, because we never wish to use a higher pressure than is absolutely necessary. It is always a disadvantage. The difficulties and dangers are always increased when we go to higher pressures; we want to use as low a pressure as is feasible, and will make the thing a commercial success.

As you are all aware, Sir William Thomson, in 1881, laid down a general rule for the economy of conductors. Summarised in the simplest form, it amounts to this, that the interest on the capital invested in copper shall be equal to the cost of the energy which is being wasted in the mains. Some years ago, Professor Ayrton read a paper before the Institution of Electrical Engineers, in which he considered that Sir William Thomson had made a mistake in this law, when it was applied to such a case as that of the carrying of power from Niagara to New York; and he argued that this law did not hold. But, as a matter of fact, the whole of the mathematics by which he supported this argument simply resolved themselves into this, that the cost of the energy which you have to take into account is really partially dependent upon the amount of copper that you have put down; that is to say, the farther the distance off from your generating station, the greater is the cost of the copper, and therefore the greater is the cost of the energy; so that, when you go to far distances, you have to allow for a greater cost per horse-power hour than you would have done if you were not going to so great a distance. This is the whole secret of the merits of the case—as I may almost call it—but Professor Ayrton thought that he had found a flaw in Sir William Thomson's argument.

I pointed this out to a gentleman who gave some lectures on the transmission of power in this hall not long ago, and he slightly misunderstood the explanation which I have just given you, and said that we had to consider as the cost of the energy the cost which that amount of energy would fetch in the market; and that, since the energy was more valuable at New York than it was at Niagara, therefore we had to add to the cost of the energy when we were transmitting it to New York. It is not so. It is simply that the cost of the energy is increased by the fact of carrying it to that distance through the copper conductors.

Now, as a matter of fact, in all these cases which come before the engineer of the transmission of power to a distance, the only really satisfactory way of applying the principle of Sir William Thomson's law is to work out the results at several different densities of current; and this involves a very considerable amount of work. You must take approximate figures in the first place, and assume different pressures of the electric current—1,000 volts, 5,000 volts, 10,000 volts, and so on—and work out the cost of sending your power at all these different pressures, and also at different densities of current in your conductor, *i.e.*, with the conductor carrying different strengths of current per square inch of section. This is the only way in which you can really arrive at the greatest economy; and it is very easy in the case of using approximate figures in the first place—you do not waste a great deal of time; it is only when you get nearly to the final result that you need go to at all accurate figures.

Now comes the question, In the transmission of power to great distances, what kind of apparatus are we to use? Are we to use continuous currents? Granted that we are to use high-tension currents, are we to use continuous currents, or are we to use alternating currents? I think that if this question had been asked a couple of years ago, you would have found that nine men out of ten would have answered you that there was nothing open for use except continuous currents. In fact, at the time that the question was in discussion in respect to Niagara, the Commissioners who sat and considered the different proposals which had been made, as nearly as possible passed a general resolution, for the guidance of the syndicate which had the concession at Niagara, that it was impossible to use alternating currents for the purpose; and yet, within this short space of time, what a transformation has taken place. I suppose that it is more due to the extremely interesting experiments which were carried out at Frankfort during the last year than to anything else, that such a change of opinion has come over the minds of men generally. I suppose that, if the same question were asked again at the present moment, not only would there not be nine persons out of ten who would say that the continuous current was the only one, but I doubt whether there would be more than one out of ten who would say so. I do not in the least wish to undervalue the continuous current and its capabilities of transmitting power at high pressure. I have seen cases where this is being done, and I feel sure that

with proper precautions it can be done well. Monsieur Thury, of Geneva, acting for the firm of Cuénod, Sautter, and Company, has erected at Genoa and Geneva, and a number of other places, high-tension continuous current dynamos. They couple them in series, so as to increase the pressure. The machines are worked up to about 6,000 volts, and they are prepared to go to greater voltages, using 2,000 volts in each machine. The machines are completely insulated from the ground, being put on piers, built up of alternate layers of vulcanised india-rubber and pieces of porcelain. The difficulty

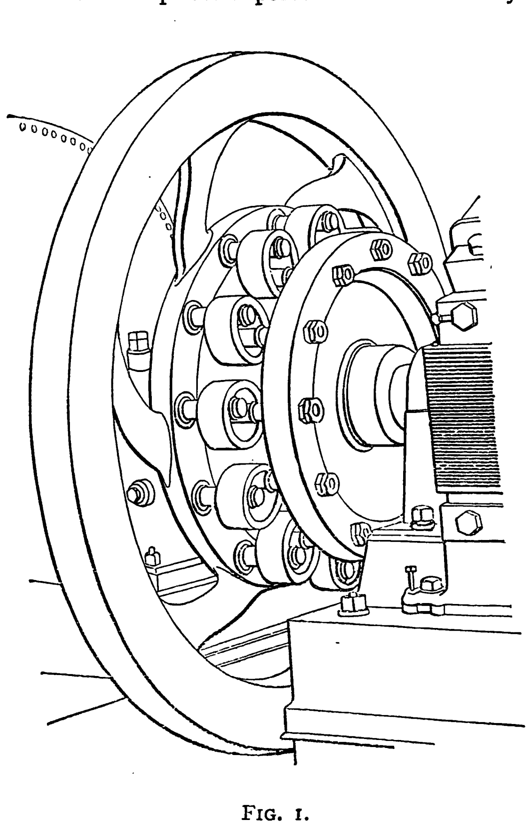

FIG. 1.

which many people thought they saw was the connection with the source of power — the water-wheel or the steam-engine — but the firm to which I allude have always used the Raffard couplings, and have been entirely successful with them; and I have no hesitation in saying that it is a very satisfactory arrangement. The Raffard coupling is an extremely simple thing, and of use when we wish to connect two axles together in a line. We place upon each of them a disc (Fig. 1), one of larger diameter than the other. An equal number of pins project through their adjacent faces, near the periphery of each of them; and these two sets of pins, which overhang each other, are connected in pairs by rings of india-rubber cut off an india-rubber pipe. The result is a flexible coupling, which is extremely valuable mechanically, and which is a perfectly insulated coupling. There is not the slightest difficulty in connecting high-tension machines to engines or turbines with this arrangement, which works perfectly well in practice.

The machines which are at our disposal with alternating currents are enormously varied in character.

First, let me speak a few words about the ordinary continuous current motor with a commutator. When we use alternating currents with them, of course it is essential to have the field magnets laminated, or made of sheets of thin iron, in order to prevent the waste due to the formation of eddy currents—Foucault currents, as they are called—in the iron of the field magnets. Even then the machine will not work with the alternating currents of high frequency; but I stated, in my last lecture, that it is practically certain that, when we come to the future of alternating current distribution, we shall be dealing with very much lower frequencies than we have been dealing with in the past. With low frequencies such continuous current motors will work extremely well. As I said in my last lecture, referring to this question, an ordinary 10 horse-power continuous current motor with laminated fields, made for 100 volts, would, owing to the self-induction of the circuit, have its output reduced about 50 per cent., because 100 volts being required for working the armature, another 100 volts would be required for getting over this self-induction; whereas, if we reduce the frequency of alternation down to the frequency which occurs in the armatures of ordinary continuous current machines, we should only be using six volts out of 100 for this purpose; so that we might say that it is within the range of practical working. Simply for distribution in a town, if the question were asked at this present moment, it is quite possible that it is this type of motor which it would be most desirable to use. The reason is that this motor, arranged for alternating currents by having its field magnets laminated, is able to do exactly the same work as the continuous current motor is at the present time; that is to say, it is able to be stopped and started as frequently as you please with the utmost convenience, and, moreover, it has the enormous advantage of producing greater

force tending to turn it at the moment when we start it, than when it is running at its full speed. The very fact of your having a larger current going through it at the start magnetises the field magnets to a greater extent and increases the turning force—the torque—which is moving it. That is a particularly desirable thing in the case of machinery in workshops and so on; but, of course, it is of the greatest importance in the case of our tramcar motors. All tramcar motors at the present time use continuous currents, but, if we were wishing to use alternating currents, it is quite probable that at the present moment this type of motor would be the most suitable and most readily available; and it is more in working tramcars and electric railways that we find the tremendous want of a powerful starting torque—that force at starting, and where the value of the series-wound continuous current motor is so great. That advantage would be reaped also by the same type of motor used with alternating currents.

I have spoken about the possibility of using alternating currents for electric railways and tramways. You might say that there is no advantage in using alternating currents for that purpose; but when we come really to examine the practical cases, such practical cases as are before the engineering world at the present moment, looking at the experience of the South London Electric Railway and looking at the Central London Electric Railway which is being planned for at the present moment, and looking at the half-dozen other lines for which there are Bills in Parliament at this moment, we find that the alternating current possesses a very great advantage over the continuous current. When we are carrying our conductors to great distances, as in the Central London Railway for instance, a distance of many miles, just as the South London Railway generating station is miles distant from other parts of the line, we find that in continuous current working at only some 400 or 500 volts we have an enormous loss in our leads, and we have an enormous expenditure of copper in our mains going to these distances. Here our conductors are not buried underground. The expense of laying our conductors is not, as in the case of electric lighting generally, the expense of going underground, and getting round pipes, and getting over other difficulties. Our expense in conductors here is simply in the copper which we put into them. Now, here we have the total gain which the alternating current is able to give us. It is altogether gain here; and if we are able to carry the alternate current by means of high tension over this long distance, and to transform it by means of that most efficient appliance, the alternating current transformer, down to lower pressures at the place where it is required for working the tramcar or the locomotive, in that case the alternating current will be giving us an enormous advantage over the continuous current. Consequently, it is extremely likely that the alternating current will be adopted in some of these schemes, which are actually before engineers at the present moment; and if such a scheme had to be worked by the alternating current at this very moment, I think that it is extremely probable that we should use alternating currents of very low frequency, alternating some five or ten times per second, using high tension in the mains, and low tension in the secondaries, and using the very continuous current machines with laminated field magnets that I have been speaking of for the purpose. That is, at the present moment, probably the solution that would be best; but the improvements and advances which are being made in the use of the alternating current with motors are so enormous, that I would not say that in a few months the facts may not be different.

I wish now to say a few words about a type of machine which has attracted considerable attention in the past, and which, for certain purposes, is probably the best which can be used, that is, the synchronizing alternating current motor. This is simply an ordinary alternating current machine—a dynamo machine for producing alternating currents. It is put upon the circuit and made to work as a motor, and it works as a motor when once you have given it its necessary speed. The motor must be going at the same speed of revolution as the generator of the electricity, otherwise this type of motor will not work.

It has been somewhat of a puzzle to a great many engineers—certainly it has been a great puzzle to the "practical" man that I was speaking of a short time ago—to understand what was the reason that some alternating current dynamos worked so well as motors and some did not. I think the question has been rendered perhaps a little more puzzling by the explanation having been so completely given in certain cases by Dr. Hopkinson. Dr. Hopkinson, some years ago, read a paper before the Institution of Civil Engineers, in which he showed that the self-induction which

is inherent in the alternating current machine tends to keep together the two machines when they are acting as generator and motor, and prevents them from getting out of step, and that, therefore, there is a certain amount of power which can be transmitted from the generator to the motor, and the motor can be made to do work. He elaborated this in an extremely interesting paper before the Institution of Electrical Engineers. As soon as these facts were established, a number of the so-called "practical" men immediately set to work to make machines with as much self-induction as they possibly could; and they altogether defeated their aims. The astonishment of many of these men was very great when Mr. Mordey read his most valuable paper —also before the Institution of Electrical Engineers—in which he showed that his dynamo machine, in which there is very little self-induction, and in which there is no iron in the stationary armature, works as a motor most admirably. He gave results which had never been excelled by any alternating current motor that had been tried, and yet there was very small self-induction in the machine at all. This was rather a puzzler for such men; and, finally, the puzzle was complete, when a comparison was made between such a machine as the Siemens alternator, which you all know, and the Mordey alternator. The Siemens and the Ferranti are both the same. The only difference between the Siemens or Ferranti alternator and the Mordey alternator is that, in the one case, the armature revolves, and, in the other case, the field magnets revolve, otherwise they are practically identical, from an electrical point of view. Yet the Mordey alternator acts most admirably as a motor, and the Siemens or Ferranti machine does not work as a motor. The reason is simply this, that the power which is being given to an alternating motor is, of course, of a pulsating character, like the current; and there are moments when no power is given to the motor at all. If, then, the motor is doing work, it requires to have a considerable momentum to get over those dead centres, and to be able to continue doing the work, and to get past those dead centres, when the generator is giving out no power whatever. Now, the Mordey alternator, in which the field magnets rotate, has an enormous momentum; but the Siemens or Ferranti alternator, where the armature rotates, has very little momentum indeed; and the consequence is, that while the Mordey alternator works admirably as a motor, the Siemens or Ferranti alternator does not. All you have to do with the Siemens or Ferranti alternator, to make it work as a motor, is to put a big fly-wheel to it. There is another method available. Suppose we take two of these alternators, and connect them together on the same shaft, and make them act as a generator for two separate currents going along separate wires; and suppose that for our motor we use two similar alternators, also coupled on a common shaft, each alternator in each pair being electrically separate, so that the one gives or receives its maximum current when the other is giving or receiving its minimum current. One of the generators is feeding one of the motors, and the other generator is feeding the other motor, and the two generators are on one shaft and the two motors on one shaft. Each of these pairs has got some dead centres. One generator and motor on one circuit have a moment when the motor is at a dead centre; but at that moment the motor of the other pair is not at a dead centre, but is at full work, so that at the moment when one motor, having no momentum, would naturally stop, the other one is driving it on. But it, in its turn, when it comes to a dead centre, is driven on by the first one which is then in full swing. This is exactly analagous to the method adopted in the ordinary locomotive for getting over the difficulty of dead centres. There we have two cylinders working the driving wheels. One alone would be sure to stop at a dead centre sometimes, and stick and refuse to start the engine; but, by having two cylinders so arranged that the one is giving its maximum thrust at the time the other is giving no thrust, they are always, when they are at rest, in a position to start the engine. That is exactly analagous to the method I have suggested in connection with the Ferranti alternator. That arrangement which I have just now described is really a way of arriving at the rotating phase motors which have created such interest in the course of the last year. This is not the exact arrangement which has been used generally in the rotating phase motors, but it is one which has been used by some makers and which works successfully. In the great electrical exhibition which was held at Frankfort last year there were a number of motors shown by different constructors, notably some by Mr. Schuckert, in which a continuous current dynamo was used, but from the wires of the armature of this continuous current machine wires were led, not to a commutator, but to

rings fixed on the shaft of the motor. Four wires equi-distant round the armature were taken to four rings, and from these he was able to take off two alternating currents going along two separate circuits to a distance, to another machine similarly fitted up. Each machine, you understand, possessed a commutator because it was a continuous current machine; and it also possessed these four rings from which the current could be collected in the form of alternating currents. One of these machines being used as a motor and the other as a generator, we had all the advantages that I have just been speaking of. We had exactly the same effect as if we had had two Ferranti dynamos joined mechanically together on the same shaft and shifted through a distance corresponding to a quarter of a period. These machines worked extremely well. They were able to start, too, though not at full load. The method of starting them was not to excite the motor in the first place, but to leave the motor not excited; the current which was created in the armature induced currents in the field magnets which tended to assist in starting, and very soon synchronism was obtained; as soon as the motor was going at its full speed the brushes were switched on to the commutator, thereby magnetising the field magnets, and the motor then ran as an alternating current motor exciting its own field magnets.

At the time that the question of utilising Niagara was very prominently before the world, I had to give my opinion as to what was the best method of transmitting the power. That was in the year 1890. I stated then that, simply adopting machinery which we had thoroughly tested, and which we knew would not fail us, the best method we could possibly adopt was that of using alternating currents, and that the best way of using alternating currents was to use synchronising motors, such as the Mordey machine. I specially mentioned the Mordey machine because I had found it work so extremely well under all circumstances. I confess that I had had, perhaps, some special advantages which enabled me to see that this was really so satisfactory a machine for transmitting power over this distance. I had not only had special opportunities of testing very thoroughly the Mordey machine, and the Siemens machine, and the Ferranti machine, but I had also an opportunity of testing the Tesla machines, which were made at Pittsburgh; and I felt at that time that the Mordey machine was the one which was most suitable for the purpose. Our object at that time was simply to transmit power. The distribution of the power through the town was of secondary importance. But even then I proposed to distribute the power through the town to large factories, which require to have their machines running all day, simply by the alternating current, transformed down from 10,000 volts to 2,000 volts, because you cannot safely carry—or, at all events then, I could not recommend that you could safely carry—10,000 volts through the streets underneath the ground. You would have it then of 2,000 volts going to the large factories. For smaller shops and places, the proposition was to convert our high tension alternating current into continuous current outside the town, and then carry it into the town for use with small continuous current motors. That was the solution at that date.

Seeing that the rotating phase motors have been such an enormous success, you may ask me why it was that I did not then consider that the rotating phase motors were the best. I am not sure that they would be the best even with the experience which has come since; but at the time I felt that, since no motors had been at work on this principle of larger size than a very few horse-power, it would be a rash experiment to go immediately up to machines, the smallest of which would be 1,000 or 2,500 horse-power; and although there was every promise in the Tesla machine, and although I proposed that we should arrange things so as to be able to introduce the Tesla machine as soon as it was made on a larger scale, I did not think that the ordinary transmission over the distance from Niagara to Buffalo ought to be done by means of this machine. And at the present moment I still think that the synchronizing motor is the best possible for that purpose. But with the enormous stride that has been made by the genius of Mr. C. E. L. Brown, of Switzerland, in the design of those machines that were shown at Frankfort, there is every reason to believe that we shall have a much greater efficiency.

Let me explain the principle, very briefly, of these rotating phase motors. Here is a diagrammatic illustration—a section of one of these machines (Fig. 2, p. 893)—in which we have four poles opposing each other, and an armature in the middle. The armature is supposed here simply to be wound like a drum armature, and to be short-circuited either at both ends, or at the commutator end. In

fact, the armature, for all practical purposes, may be supposed to be simply the ordinary drum armature of a Siemens' machine, with the commutator wound round with a bare copper wire, so as to be short-circuited at that end. The armature conductors are closed upon themselves, and have no current coming in from the outside. There are two currents coming to the motor from the generating station in different phases. One current circulates round the two horizontal magnets, their polarity, at any moment, being of opposite kind. The other current circulates round the two vertical magnets. The one current is at the maximum when the other current is at the minimum, and one current is always just a quarter of a phase in front of the other current. The consequence of this is, that the magnetism which is induced in the armature

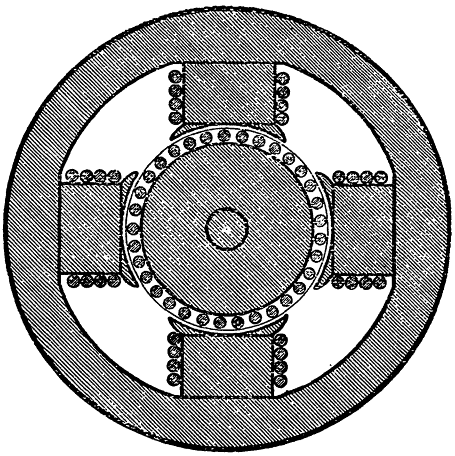

FIG. 2.

will at one moment have a horizontal direction; a little later it will have a vertical direction; a quarter of a period later again, it will again have a horizontal direction, but opposite to what it was before—that is to say, the polarity will be reversed, and so on. It will be seen that, as the magnetism of any pole continually changes gradually from zero to a positive maximum, again through zero to a negative maximum, every complete period; and that the successive poles round the machine differ from each other's condition by an amount corresponding to a quarter of a period; there will be what is equivalent to a continual rotation of the whole magnetic field round the axis of the machine. The lines of force, in cutting through the wire of the armature, induce electric currents in the wire, of course; and since the armature opposes the creation of these induced currents in the wire, a natural mechanical opposition is offered to these wires being cut by these magnetic lines of force; and the consequence is, the armature is carried bodily round, and tries to turn round at the same rate at which the magnetic field is travelling round, in which case the conductors would not be cut at all by the lines of force. That is the general principle of the machine, which was independently invented by Ferraris, of Turin, and Mr. Tesla. The results of the official experiments which were made at Frankfort have not yet been published, and consequently we are hardly in a position to speak of the value of them; but I may say that we have not the slightest doubt that this system of multiphase transmission is an extremely effective mode of transmitting power, and that it opens a new field, and is equally suitable for distribution and for transmission, and in that way has an enormous advantage over the simple alternating current system with synchronizing motors. It has all the advantages of simple alternating currents, in that we can use low-tension dynamos, which are perfectly safe things to deal with, and which can be made of thoroughly mechanical construction; we can increase the pressure by means of a transformer, and carry the power to a distant station; lower the pressure there to such a pressure as is convenient for distributing through a town, and then take it off at the houses where the motive power is required, and drive our motors. That is to say, it has all the elasticity of the ordinary alternating current system; and its motor has the enormous advantage over the synchronizing motor in that it is a machine which is suitable for placing in workshops—one which you can start and stop as often as you please. One of the greatest uses of electrical motors in workshops, with which I am acquainted, is their use for cranes, especially travelling cranes. There are many other cases where it is highly useful for replacing shafting and for the working of machinery. In all these cases we need to be continually starting and stopping the motor. We cannot leave the motor continually running; and it is essential for these purposes to have some motor like this rotating phase motor, in which we can start frequently and effectively. We have had no tests published of the Frankfort trials as to the power of starting, but I may perhaps interest you by giving you, in concluding this lecture, a few results of experiments which I made this afternoon with such a rotating

phase motor, as I do not think that any results have been published at all. I will only just give you one or two results. I will give you one just to show you what work the machine was doing. It was not doing a very great deal, but I will give you an example of what it was doing. The alternating generator was driven by means of a continuous current motor, the current being supplied to it from the mains of the Westminster Supply Company. That alternating generator supplied alternating currents to one of these rotating phase motors. That motor in turn was caused to drive a continuous current dynamo machine, and it supplied a number of lamps. We were able to measure the volts and ampères which came in from the Westminster Company, and the volts and ampères which went to the lamps; and we could get an idea of the amount of work which was being done by this motor.

With the first continuous current motor we had 102 volts in one experiment and 39 ampères. And on the lamp circuit where the work was being done we had 89 volts and 9½ ampères. That shows that we were getting something over a horse-power from the motor. That is the only reason that I put down these figures. You must not take these figures as representing the efficiency of the alternating motor in the least degree. They give us no information on this, because, in the first place, it was an inefficient motor which we were using to drive the alternator, and it was an extremely inefficient dynamo which we were using to generate the current for the lamps, so that we had really no test of efficiency whatever. But it gives you an idea of the horse-power which we were using. The motor was a motor which was giving us off about 1 horse-power in the lamps, but it was working up to a higher figure. Now an interesting experiment was to find what power there was at starting, and I found that on a pulley having a diameter of about five inches, there was a pull of about 40 lbs., when the alternating motor was supplied with current at the same pressure as in the previous experiments; that is to say in the ordinary working of that alternating motor as at that time, we would get a pull of about 40 lbs. on a pulley of five inches. The speed at which we were going in this experiment was 1,380. Now the pull at 40 lbs. which I found on the pulley would have given us 2 horse-power at that speed. Consequently the torque at starting was extremely good; and although this is a very rough experiment, it is of the greatest interest to myself to have the measurement of the starting torque with such a motor, because I have not been able to get any other actual measurements of any sort whatever. We shall get more accurate experiments very soon no doubt, but this is the first step in the right direction.

Miscellaneous.

TEA CULTURE IN ASSAM.

The report on tea culture for 1891 issued by the Assam Government is quoted in the *Board of Trade Journal*:—

"Following the practice of previous years, figures are given separately for each sub-division, in addition to the totals for each district. Cachar sadr still heads the list with the largest number of gardens (138); Lakhimpur sadr comes next (130); the former also shows the largest area under tea and the largest out-turn. In the Brahmaputra Valley, North Lakhimpur shows the highest proportional yield of 572 pounds per acre, while in the Surma Valley, Habiganj heads the list with 649 pounds per acre.

"The total number of gardens borne on the registers at the close of 1891 was 828, against 867 at the close of 1890, and thus showed a net decrease of 39. There was a decrease of 43 in Kamrup, as against an increase of 10 in Sibsagar, and 14 in the other districts.

"The apparent increase of 10 gardens in Sibsagar is due to the inclusion, in this report, of nine small gardens in Jorhat, which were excluded from the previous year's reports, owing to the managers not having supplied the necessary statistics in those years. The decrease is largest in Kamrup, where 28 abandoned gardens have been struck off the register this year. Besides these, 13 gardens in this district, which were not worked, owing to depression of trade, and were hitherto shown under head "Estimated," have been excluded from the present report, in accordance with a suggestion made by the Commissioner of the Assam Valley Districts. Assuming that the above 13 gardens were included among the 22, shown as unworked in paragraph 5 of the preceding year's report, and excluding the nine gardens in Sibsagar, included for the first time in the report, and referred to above, the actual reduction in the number of gardens in the whole province would amount to 35.

"The large increase in Cachar is attributed by the Deputy Commissioner to an attempt made to include in the tea register the areas that have been newly taken up annually by tea planters. In the Brahmaputra Valley, Kamrup shows a considerable decrease in the area held by tea planters, which is due to 41 gardens having been removed from the register

during the year (13 unworked and 28 abandoned). The decrease in Darrang is accounted for by the four gardens closed, and that in Nowgong is due to the readjustment of the boundaries of the waste land grants by the cadastral survey, no new land having been taken up during the year. The increase in Sibsagar has not been explained, while that in Lakhimpur is attributed to the new gardens opened during the year.

"The statement below gives for the last six years the areas under mature and immature tea plants, and the total area held by tea planters:—

Year.	Under Mature Plants.	Under Immature Plants.	Total Area of Land held by Tea Planters.
	Acres.	Acres.	Acres.
1886	170,138	33,855	934,134
1887	177,900	33,179	950,171
1888	188,329	28,347	955,499
1889	196,689	30,560	1,000,665
1890	200,658	30,380	994,497
1891	208,407	33,416	996,746

"The above shows an increase under all the heads, that in area under mature plants being a steady one. The increase in area under mature plants, which has been general in the Surma Valley and in the upper districts of the Brahmaputra Valley, is due to 'immature' plants passing to the category of 'mature' after their fourth year of growth. Silchar, Habiganj, Gauhati, Nowgong, Sibsagar, and Golaghat show a decrease in area under immature plants, which is partly due to the above reason, and partly to extensions not keeping pace with the progress of plants from immature to the mature stage.

"In the statement below figures are given showing the total area under cultivation for the last two years:—

District.	Total Area under Mature and Immature Plants.		Increase or Decrease.
	1890.	1891.	
	Acres.	Acres.	Acres.
Cachar	56,562	58,793	+2,231
Sylhet	43,196	46,428	+3,232
Khasi and Jaintia Hills	30	30	—
Goalpara............	397	425	+ 28
Kamrup	6,361	5,131	−1,230
Darrang	21,327	23,134	+1,807
Nowgong	11,868	11,886	+ 18
Sibsagar	54,940	58,370	+3,430
Lakhimpur	36,357	37,626	+1,269
Total	231,038	241,823	+10,785

"The increase in Cachar, Sibsagar, and Lakhimpur is due to recent extensions. The Deputy Commissioner of Sylhet attributes the large increase in his district to the extensive areas put under tea year by year in all sub-divisions, which have now come under the category of 'mature.' No reason has been given for the increase in Darrang, except that the figures are only approximate, estimates having to be made for 11 gardens, some of which have not furnished returns for many years. The variations in other districts have not been sufficiently accounted for.

"The total out-turn of tea in 1891 is reported as 90,399,362 lbs., being an increase of 8,280,110 lbs., or 10·08 per cent. over the previous year's figures.

"The following statement compares the figures furnished by the Indian Tea Association and the Trade Returns with those reported by the Deputy Commissioners:—

"Out-turn according to India Tea Association.—1890, Brahmaputra Valley, 45,416,721 lbs.; Surma Valley, 31,472,703 lbs.; total 76,889,424 lbs; 1891, Brahmaputra Valley, 50,967,373 lbs.; Surma Valley, 38,696,664 lbs.; total, 89,664,037 lbs.

"Out-turn according to trade returns.—1890, Brahmaputra Valley, 46,703,973 lbs.; Surma Valley, 32,016,795 lbs.; total, 78,720,768 lbs.; 1891, Brahmaputra Valley, 46,418,277 lbs.; Surma Valley, 34,563,950 lbs.; total 80,982,227 lbs.

"Out-turn according to Annual Tea Report.—1890, Brahmaputra Valley, 48,144,401 lbs.; Surma Valley, 33,974,851 lbs.; total 82,119,252 lbs.; 1891, Brahmaputra Valley, 50,643,374 lbs.; Surma Valley, 39,755,988 lbs.; total 90,399,362 lbs.

"The trade return figures are, as usual, the lowest, and those furnished by the district officers the highest. The difference between the latter and the Indian Association figure is not, however, so large this year, being only 735,325 lbs., as against 5,229,828 lbs. in 1890. All the three sets of figures point to a growth in production which, moreover, has been continuous for some years.

"Thus, the yield in all districts, except the Khasi and Jaintia Hills, Kamrup, and Nowgong, has increased. Darrang, which showed a slight falling off in 1890, has much improved this year, while the decrease in Kamrup, which is attributed to short rainfall and want of labour, still continues. The same reason is given for the decrease in Nowgong. The large increase in Goalpara, viz., 29·43 per cent., against 1·49 per cent. in 1890, is rather curiously explained. For instance, while one manager puts it down to the 'peculiarity of the season,' and 'uneven distribution of rainfall,' another says, 'the season has been an exceptionally good one, and has increased the yield.' The Deputy Commissioner adds as his own opinion—

"I believe the season was a very bad one for want of sufficient rain throughout the year. The increase in the yield may have been caused by the increase in the number of mature plants."

PRODUCTION OF INDIA-RUBBER IN NICARAGUA.

India-rubber is obtained in Nicaragua from the *Siphonia elastica*, a tree from fifty to sixty feet in height, and no india-rubber has as yet, it is said, been obtained from any other source. The native name for rubber is *ulli*, and the United States Consul at Managua states that this was a term applied to it by the Aztecs. The Spaniards called the collectors of it *ulleros*. Some authorities in the country claim that the rubber tree of Nicaragua is not the *Siphonia elastica*, but the *Castilloa elastica*. There are several methods of obtaining the rubber employed by the hunters, but the principal are those described below. The large rubber trees are generally felled, and incisions about 2 inches deep and 2½ inches wide at the top are made round the tree at distances of about a foot apart, and the rapidly flowing milk collected, through funnels formed of leaves, into calabashes, each capable of holding from three to five pints, or in holes made in the ground and well lined with leaves. Another method employed is to cut into the tree near the top and down to its base, one, two, or three vertical channels, according to the size of the tree, through the exterior bark into the lactiferous vessels, and frequently through these vessels into the woody fibres; then cutting numerous oblique channels on each side of, and connecting with, the vertical ones. This work requires ladders, which the rubber hunters improvise either by using the vines on the trees which they intend to scarify, or cut from the numerous meshes of vines found handy in the forests; by these the *ulleros* ascend the trees and commence their work near the top, and continue cutting one or two vertical, and numerous oblique connecting channels uninterruptedly, until they have completed them. They work rapidly in order to keep in advance of the fast flowing milk. The milk is conducted from these channels by the means referred to above. A third method used by the rubber hunters is to scrape off the outer bark of the trees with a *machete*, commencing eight or ten feet above and extending down to within one or two feet of the ground. Clay alone, or a vine and clay, are placed around the tree, inclined so as to form a ridge about two inches high on the lower edge of the scraped or bark-removed part of the tree. This guard is sufficient to direct the rapidly flowing milk or emulsion into the receivers at the foot of the tree. In order to make the milk coagulate rapidly, the Indians or rubber gatherers make a decoction from the vine which they find twined around the trees, and this has been found the most efficient means of producing coagulation. This decoction on being added to the milk, in the proportion of one pint to a gallon, coagulates it to rubber, which is made into round flat cakes. Sometimes the fresh milk is mixed with the coagulating decoction, and then heated up to between 160 and 170° Fahrenheit, in the calabashes, and with a result apparently of a more elastic and less gummy india-rubber than that obtained by any other process. As the number of rubber trees becomes less, the methods employed in gathering the rubber become different. A few years ago the trees produced from ten to twenty gallons of milk, and the rubber hunter would then take the milk and put it into a large hole in the ground and make a cake of it, known as *torta*, but now that the trees do not yield a great quantity of milk, the plan of making a hole in the ground is fast being done away with. The best rubber is considered that which is taken from the long channels, which the *ulleros* cut in the trees, after the milk has been allowed to remain in the channels from one to two weeks. The rubber is known as *borricha*, and it is considered to be superior to all other because it contains less water. The natural supply of india-rubber is yearly decreasing in Nicaragua. The cause of this is the habit of the natives, until lately, of cutting down the trees, thinking that they could thereby secure more milk. The Government attempts no supervision of the forests; anyone may cut the trees, and great destruction is caused by the young trees being tapped as well as the full-grown ones. Consul Newell says it is an incontrovertible fact that, so far, at least, as Nicaragua is concerned, the rubber tree is susceptible of cultivation, and in the district of Managua there are large tracts of land suitable for growing rubber trees. The rubber section of Nicaragua is that portion extending from the mountains in the vicinity of Chontales, the north-eastern part, to the Atlantic coast, and it is the opinion of those persons in Nicaragua who are interested in rubber production, that the cultivation and improvement of rubber plantations would be very profitable.

General Notes.

ARTISTS' COLOURS.—With reference to the recent discussions in the Society as to the permanence of modern pigments, it may be interesting to quote the opinion of Sir Frederick Leighton, as expressed to the writer of an "interview" lately published in the *Strand Magazine*:—"I consider that the colours used to-day, if properly prepared, ought to be far better and much more durable than those of the past. In the days of Sir Joshua Reynolds and Wilkie, during the reign of asphaltum, a colour used very largely then but now quite out of use, the pictures suffered very much. Although I have been painting in oil exactly fifty years, I have only had one single accident happen with a pigment."

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

MEETING OF THE EXECUTIVE COMMITTEE.

A meeting of the Executive Committee was held on Wednesday, 7th inst. Present:—Sir Frederick Abel, K.C.B., F.R.S., in the chair; Alfred Carpmael, R. Brudenell Carter, F.R.C.S., Francis Cobb, James Dredge, John O'Connor, with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

Proceedings of the Society.

CANTOR LECTURES.

DEVELOPMENTS OF ELECTRICAL DISTRIBUTION.

By Prof. George Forbes, F.R.S.

Lecture IV.—Delivered February 15, 1892.

In my last lecture I was dealing principally with the question of using water power in connection with electric lighting and electric power. There are two engineering problems, important to engineers, in connection with the use of water power; one is where we are using it simply for lighting up a very small place, and one frequently has to deal simply with the lighting-up of a single country house. The extreme case, on the other hand, is the transmission of power to great distances, where you want to utilise a waterfall, and bring the power into a town and use it there for motive power or for lighting. These are two very distinct problems, and there are several points in each of them that need particular attention. It may be worth while to introduce a word of caution in connection with the use of water power for lighting country houses. I have found from experience that the very greatest caution is necessary in utilising water power that may seem to be perfectly available. In the first place, it is generally extremely difficult to find out what is the exact amount of power which can be obtained from the source of the supply. Of course the water power in this country is generally superabundant in winter, and diminishes in summer. That is a fortunate thing for us, and suits the demand for light; but it becomes extremely doubtful whether the supply of water which we can get in the very driest time of a dry summer will be sufficient for our purposes. I may say that, whenever it appears, from observations that you may take at any one time, that there is the slightest doubt it is the most injudicious thing to set up turbines and plant for utilising the water power without having taken measurements of the flow of water, at least during one summer, and thus judged as to the probability of the supply during a particularly dry summer. But there is another equally likely catastrophe to happen, which is far more serious and important, and that is that in a great many places, where it appears perfectly certain that we shall have enough water during the whole of a dry summer, there may come on a heavy frost in the winter, which will freeze up the source of a stream, and prevent us from getting our power in mid-winter. The fatal effect of such a thing is evident, because it is in mid-winter that we want our light most; but it sometimes happens that a small burn that we intend to use for electric lighting, which the inhabitants around may tell you certainly never freezes, and that the flow in winter is always superabundant, may sometimes be found to freeze, and you are deprived of water power in the very middle of the winter. In such cases, however, it very frequently happens that it really would be a saving of expense to introduce turbines, besides having an auxiliary boiler and steam-engine for cases of emergency. It is a large additional expense to the original plant, but it is in most cases extremely useful and very economical, when we consider the saving that the water gives us in the consumption of coal during the greater part of the year.

But there is another point of economy which sometimes has not enough attention paid to it, and that is when the source of water power is not exactly on the premises or where you want the power to be used. It very often happens, in a country house, for instance, that the power is at a distance of, say, half a mile from the house. Now, even the distance of half a mile is serious, when you come to calculate the size of the conductors which will be required to convey your current from the source

of power to the house. Too often people have gone upon the assumption that the cables would not have to be very large, and have been disappointed in this way, and have thus been led to very considerable expense.

With regard to the extreme case of using water power for transmission to a distance, and, it may be, subsequent distribution through a town, I spoke pretty clearly on the last occasion; and while at the present moment most cases of transmission would be best done by means of the alternating current, I can quite see cases where the continuous current is the most applicable, and there is no reason why we should not transmit our 10,000 volts or so by means of a continuous current for such purposes, only taking far greater care for matters of safety, because the dangers of a machine with a commutator are very much greater than with an alternating current machine. Of the means available for using the alternating current, as I have stated, there are two which may be considered, at the present moment, as decidedly the best. The one is by means of synchronizing generators and motors, which are ordinarily alternating current dynamos, working synchronously with each other; and the other is by means of the rotary phase system of transmission. I pointed out, at the end of the last lecture, that, while light alternators will not work well as motors when they are used singly, with a simple pair of conducting wires, you may use them in pairs, receiving two different currents in different phases from a similar pair acting as generators, one receiving its maximum when the other is receiving its minimum; that that arrangement enables us to get over the dead centres; and that such a machine, if it is extremely light, will start with a good pull from the beginning, and will do transmission work extremely well. Thus it appears that two Ferranti dynamos arranged in that way will make a generator of two currents, and will work as a motor also, and will work well, and will start well as a motor; whereas the Mordey alternator, which I contrasted with it in the ordinary way of working, has a very massive rotating part, and in consequence of that, it will not start as a motor so well as a light machine, when we are using two separate currents. Thus we have the curious fact that the heavy Mordey machine is the better as a synchronizing alternator of the two, whereas the light Ferranti alternator is the better one, where you are using two currents in different phases. Lately, in America, the dynamos which had been used for generating continuous currents for tramways by the Westinghouse Company have been fitted with rings for use instead of the commutator; four rings for taking off two alternating currents, one giving its maximum when the other current is giving its minimum. These large powerful machines have been working admirably as motors; they start very readily indeed; and of course continuous currents can be then taken off, on the same sort of principle as was shown by Mr. Schuckert at the Frankfort Exhibition, which has been talked of a good deal since. That machine has been very largely adopted indeed, and has been doing admirable work.

Coming now to treat of another matter in connection with water power, I wish to draw attention to what has been done in Switzerland in the way of utilising water power. Last summer I had the advantage of travelling with Professor Unwin through Switzerland, our object being to study the various cases where the natural power of water had been utilised for transmission to a distance, whether the means for transmission was electrical or by wire rope, or by any other means. I regret extremely — no one can regret more — that Professor Unwin was not able to give his course of Howard lectures here on the transmission of power to a distance. Those lectures would not only have been of the greatest interest to everybody who would have been here to hear them, but also of the utmost importance to engineering science generally at the present moment, when so much attention is being given to the transmission of power to a distance in every way. However, we found, as is well known to all of you, that Switzerland is quite in the front rank in the utilisation of water power, and in its transmission, whether it be by electricity or by any means. The engineering talent of Switzerland, compared with its population, ranks higher, I should say, than that of any other country in the world, whether we speak of its roads, its railways, or its large works for the utilisation of water power. There were two towns in Switzerland which attracted our most particular attention from the somewhat similar plans which had been adopted, and the admirable way in which they had been carried out, viz., Geneva and Zurich; and since they are so similar in their general principles, I will confine my attention principally to speaking of the Geneva works. In Geneva the power of the River Rhone, where it leaves the Lake

of Geneva, is utilised, and the fall varies from 6 to 12 feet. In Switzerland the maximum flow of water is in summer, and not in winter, as in this country, owing to the melting of the snow being the cause of the floods. Very large turbines must be erected, of course, with that low fall, and a number of turbines (nearly 20) have been erected to give in all 6,000 horse-power. This is a very large work, and involved a very big capital expenditure, but it certainly is to the credit of the Swiss Republic that when they vote money for large works for the State, the money all gets into the work. The same is not the case with all republics, and it is through the combination of great engineering talent, and this strict supervision over the expenditure, that these great works have been accomplished. The consequence is that, although an enormous capital expenditure has been necessary at Geneva, there is an ample return on the money invested.

The way in which these turbines are utilised is to supply motive power to the small factories that are distributed all through the towns. Watchmaking and other trades that are carried on in Geneva require a deal of small power, and the way in which this is done is by utilising these large powerful turbines with a small head of water to pump water up to a distant reservoir some three or four miles off, which gives a very large head of water, and then from the pipes connected with the reservoir other pipes are led throughout the town to distribute the power, and from these motors are supplied direct; the charges for the motors being generally made at so much per horse-power. This system is exceedingly effective, and a most valuable report has been drawn up upon the subject by Colonel Turrettini, who superintended the work, and I might have given you a great many extracts from that report containing much interesting information, but my reason for drawing attention to it is not so much to describe the details of the hydraulic work as to draw subsequently a moral from the manner in which its source of water supply has been utilised for the electric lighting of the town. This is carried on by a separate company, and you might naturally have thought that it would have been best for them to create their own power. The central station is situated on an island in the Rhone, close to the large turbines of the town, and it would have been natural, you would have thought, for them to utilise the power that is there available. They do not do so. They found that the terms upon which they can rent power from the town were sufficiently moderate to make it worth their while to do so, and to set up their electric lighting works independent of any source of power, although they were in the close neighbourhood of these turbines, and might have had turbines of their own. We consequently arrive at this somewhat anomalous arrangement as it might seem to you. There are powerful turbines on the Rhone pumping water to a reservoir three or four miles distant; the water from that reservoir comes back to within about 100 yards of the place where it was taken from, and is there made to pass through other turbines to generate power for driving the dynamos which light the town. At the first glance, it seems almost incomprehensible that there could be any economy in that; that instead of using the power on the spot you should first pump it to a great distance, and then use the water from that distant reservoir. In that case, one might ask why it would not do to put a steam-engine down, pump the water to a distance, and then use the water when it came back to drive your turbines; but, although it seems impossible that that could be a source of economy, as a matter of fact such an arrangement is an economical system, and the reason for it is that, when we are using steam-engines direct, as I pointed out in my first lecture, we are losing a great deal of the value of the coal that we are burning, first because the engines are during a large part of the time running light, but also because the boilers are consuming far more coal for the amount of work that is done than they would be if those boilers were continually working; so that really cases may arise where there is a decided economy in putting down a less number of boilers and steam-engines than would be required to give off the maximum current that may be required from a central station, and to use these engines for continually pumping water up to a height, if there could be found a place where a reservoir could be made in the neighbourhood of the town, and then use the water from that reservoir to flow through turbines, and drive our dynamos.

There are many places in this country where such a system is of very great economy indeed; and in any case where there is economy effected, I may say that the arrangement is an admirable one, and is extremely satisfactory in working. Any person who has ever used, or seen used, water turbines in a central station for electric lighting, must be convinced of the great facility it gives to the

proper management of the central station. The whole space occupied by the machinery is so very limited, the machinery is so easily regulated, the place is so clean, and so free from noise, that very little attendance is required, and the attendance is easily given and easily devoted to the purposes required. So that really, I can say from past inspection of such electric lighting stations driven in that way, a single attendant is able to manage the turbines, the dynamos, and the switches, and everything, and most of the time he has really nothing to do. The difference between this and having engine-drivers and stokers continually at work, and the difficulty of communicating orders, by shouting, it may be, owing to the noise, and the general discomfort of managing a very large station, instead of having it all compact in one place, is very striking; so that wherever such an opportunity of using water power occurs it is very desirable to take advantage of it. Now, as a particular example, I will mention the case of the city of Edinburgh. There it is possible to use the heights which surround the town for collecting the water. In the immediate vicinity of that town there is the hill known as Arthur's Seat, at a height of 800 feet above the sea. There is on this hill a loch already, called Dunsapie, which holds water enough to supply 1,000 horse-power for two hours. Anyone who is conversant enough with central station work will see that here there is the means of supplying sufficient power for doing the work of a large central station—in fact, driving one central station by means of the water power which could be derived from that reservoir; but with the utmost facility a dam can be built across a gully which there is near the summit of the hill, giving us a far greater height, and this dam would cost but little, owing to the natural construction of the hill; it would be invisible from all parts surrounding Edinburgh, save only in one direction, and even in that it would not be on the sky line, and would not be an injurious feature in the landscape, whilst to those who go up to the summit to enjoy the view, the lake which would be formed would be an extra attraction. There is really nothing in the beautiful features of the place to prevent that being done, and thus the amount of power which could be stored would be fully doubled. For working a station which requires the maximum of, say, 1,000 horse-power, we do not require an average in many cases of more than about 150 horse-power. What, then, we should have in this station would be engines and boilers for 150 horse-power continually working day and night, from week's end to week's end, employed in pumping water up through pipes to this reservoir on Arthur's Seat. In connection with these pipes, at or near their lowest part we should have turbines driving dynamo machines, for the distribution through the town. Instead of being obliged to have engines and boilers of 1,000 horse-power we should have them of only 150, thus saving an enormous amount in capital expenditure. If we do not require to build a dam, as we do not in the first instance, using the Loch Dunsapie which is there, the only serious item to consider, to be put against the boilers, is the pipes. These would come to something like £2,000, but the saving in capital expenditure on the whole is very great. But it is not only the saving of capital expenditure which is important, it is the annual saving in the coal bill. The pumping up of this water by an engine perfectly continuously can be done in the most economical manner that any work with steam-engines can be done; whereas, on the contrary, we know that in central station work for electric lighting we have one of the most uneconomical methods of using coal possible. We can get 1 horse-power available on the turbines, including the losses in pumping up and the losses in the turbines, for certainly very little over 3 pounds of coal per horse-power per hour used in the boilers; whereas in many central stations, as you know, they are going up to 10 pounds, 15 pounds, or even more of coal per horse-power per hour. There is then undoubtedly a most enormous saving in fuel besides the saving in capital expenditure, and for these reasons, wherever such a system is available, it will be desirable to adopt it rather than to put down the whole plant necessary for generating the maximum current which may ever be required. I worked out this pretty fully in the case of Edinburgh for my own satisfaction, and have already brought the matter before the authorities there, and I hope to see some such scheme adopted, not only there but in many other towns also where equal advantages are offered. In working out the figures I may say that the actual expenditure is very little more than half what it would be if we were putting down steam plant for the whole work, and the savings which are effected in attendance and fuel are, even when we are using coal for generating steam, very great indeed. It saves about one-third of the expense, not including

of course the expense of distribution of electricity, and so forth.

If I had to be contented with simply what I have told you up to the present moment, such a scheme would be of the utmost value in cases where it is applicable, but there is another source of economy which can be introduced, and for which this system which I have advocated is perfectly suitable. This leads me to the part of the subject to which I wish to draw your attention this evening, and that is the employment of destructors for utilising the refuse in towns—the ash-bin refuse, which at present costs an enormous sum of money to be got rid of, and which, in many towns, is simply tipped in the outskirts, and becomes a source of disease and danger, especially when the town expands, and building operations commence in the region which has been used as a tipping ground. The whole question of the disposal of town refuse is one of importance. It is one to which, I need hardly say, electrical engineers, as a general rule, have not paid much attention. I daresay there are comparatively few here who have really gone into the question of the use of destructors, and I should not be surprised if there are some present who have hitherto been ignorant of what a destructor was; in fact, a very well-known electrician last week, after I announced that I was going to speak about destructors, and the considerable importance that I attached to them, came and asked me, after the lecture, what it was I was going to talk about.

Several years ago, when I was advising the Vestry of Paddington about the electric lighting of their parish, I found that they were in a serious difficulty in dealing with their ash-bin refuse, and I was led immediately to see the importance of studying the whole question. I then made a personal inspection of most of the destructors which were then in use, and I was so enormously impressed with the importance of the subject that ever since then I have neglected no opportunity of seeing the work which is being done in this direction in the different towns.

Let us see what the problem was that Paddington had to face. Every year they collected something like 20,000 tons of refuse of this character, and since the population of Paddington is 112,000, we may assume generally that something like this proportion exists in nearly all towns. It so happens that the proportion of ash-bin refuse to population does not vary very much with the different towns. Now it will strike you, as it has struck me, as a very wise provision of Nature when I tell you that if that refuse were properly burned, and if it were used in the most economical way, it would be found that (assuming the proportion of lighting required for such population to be, as has been very generally assumed, one lamp per head) the amount of refuse provided by any population is almost exactly as much as is required to supply the illumination by means of the electric light to that same population.

Now let us see what this refuse is which is collected every year in Paddington. Out of every 10,000 tons we find that ashes constitute 5,260 tons, breeze or cinders 2,880, what is known as soft core, viz., animal and vegetable refuse, 1,420, hard core, which is pottery and that sort of stuff, 290, actual coal 15 tons, bones 25 tons, rags 42 tons, iron 35 tons, brass and pewter 3 tons, white glass 7 tons, and black glass 23 tons. Those are the materials that have to be got rid of. I have given you these figures as I found them at Paddington, because Paddington is more able to give accurate information on this subject than almost any place I know of; because in Paddington, instead of simply taking away the refuse and dumping it somewhere or other, as is done in many towns, they found it was more economical to sort out the different materials in this way, and sell some of them for different purposes. They were able to get a sort of price for a great many things. Coal always had its use, and breeze and ashes could be sent to the brickfields, and they were able to recoup themselves to a certain extent, so that really the actual cost of getting rid of it in the parish of Paddington was only about £1,000 per annum. In other places it is very much more, but in any case, the manner of getting rid of it was bad. There was a large proportion of stuff which could not properly be rendered harmless, but which had to be disposed of in some way. The quality of the refuse varies with the different towns. For example, in this you see there is no sludge of the streets, and no other objectionable matter which may be found in other places. In Manchester, for example, out of 10,000 tons there are 6,450 tons of ashes and excreta, which are collected in pails, dust and cinders 3,455 tons, fish and bones 15 tons, dogs, cats, hens, rabbits, &c., 5 tons, boots, rags, hats, paper, &c., 5 tons, vegetable refuse 5 tons, glass, pottery, bricks, &c., 60 tons, old iron and tin-ware 5 tons. That makes the 10,000 tons.

In addition to that, they have to dispose of slaughter-house refuse and market refuse, and street sweepings, amounting to 2,900 tons, in addition to every 10,000. The aggregate quantity of burnable material is 70,000 tons. It is found that the quantity of coal which is collected in the ash-pit refuse varies with different times of the year, and with different districts. It is more in the richer residential districts, and it is also more in winter. In summer there is more vegetable stuff, which is less combustible, and there are some places in which the ashes are exposed to the rain, in which case the combustibility is affected. But then see another wise provision of Nature—the coal and cinders are more frequent in winter, when we want most light, and vegetables are less frequent then, and they are less combustible materials.

The history of the use of destructors is comparatively modern, and the very first ones that were attempted were not very successful. The cause of their failure was almost altogether due to insufficient draught; and in almost all cases where a great improvement has been made in them, it has been by the introduction of greater draught. In the first destructors the furnace was fed from the front, just as the ordinary furnace of a boiler is, but that has been completely done away with now. During the last 20 years, one type of destructor has been most generally used—that is, the type known as Fryer's destructor—which has been made by Messrs. Manlove, Alliott, and Co., of which I shall have more to say later on.

The first destructors which were put up on any scale were in Water-street, Manchester. Eight furnaces were put up, and these were the first that were any practical success. They consumed $28\frac{1}{2}$ tons each per week of $5\frac{1}{2}$ days. They were 8 ft. 6 in. $\times$ 4 ft. 3 in. wide, and 6 ft. 3 in. high from the fire bars up to the crown of the arch; 5 feet of the length was occupied by fire-bars, and 3 feet with the hearth. There was a bridge at the back, and a descending flue down into the main flue for carrying off the gases.

The next place that was furnished with destructors was the Montague-street Wharf, Birmingham. These destructors have been in use for a long time, but they have been combined with the process employed there of converting excreta into profitable manure for agriculturists, and consequently the efficiency of the destructors has been considerably impaired. It was necessary there to keep up steam for the treatment of the excreta, and steam was got up from these furnaces by putting the boilers directly over the furnace. In consequence of this the combustion is very imperfect. The large cooling surface of the boilers impedes the combustion in an effectual degree. In most cases where boilers have been used to generate some steam, the boilers have been put away, and after the gases have passed through the flue they then pass by the boiler, and the error has been in the opposite direction. At Birmingham the fault is placing the boilers on the furnace, so that there is no proper combustion; in many other places, take Southampton, for example, as a notable case, the boilers are put in a place where they cannot benefit from the maximum heat.

After these destructors had been introduced, the Fryer destructor came into more general use. Fig. 1 (p. 903) shows this destructor. The furnaces there are 9 feet long, 5 feet wide, and covered by a fire-brick arch 3 ft. 6 in. high. The furnace has an inclination of 1 in 3, four feet of the bottom being a fire-brick hearth, and the other five feet of fire bars. The furnaces are arranged in two long rows, back to back, with a large flue running underneath and between the rows, as shown in section in the diagram; and the air is admitted beneath the fire bars. At its upper end the furnace is divided in two longitudinally by a short vertical wall. On one side of this division, the hearth is inclined at a greater angle than the rest, as shown in the left-hand furnace on the diagram, and immediately over this is the opening through which the refuse is shovelled down, after being tipped over on the top from the carts which carry it, the hole being shown covered by a flat cover. On the other side of the dividing wall is the opening to a flue leading from the furnace to the main flue, as shown in the right-hand furnace on the diagram. Each furnace then has two outlets at its upper end, side by side, through one of which the refuse is fed from above; the other forming the exit through which the products of combustion pass to the main flue. Besides these, there is, in a few of the furnaces, another hole right over the hottest part of the furnace (shown in the left-hand furnace on the diagram), which is generally covered, but can be opened when required. This hole is usually called the mattress hole, and is used for putting in infected bedding and other material, such as carcases and other slaughter-house refuse, and other such like matters which have to be utterly destroyed. The main flue is sometimes made extremely large, so as to allow dust to settle,

and baffles are sometimes introduced into it to increase the facility of the dust settling. Sometimes at the end of the flue there is a very large chamber put for the same purpose, through which the gases pass before entering the chimney. These are the chief points in connection with the Fryer destructor.

One of the chief defects of this destructor is that it is possible for the air which is admitted to blow towards the flue and carry half-burnt stuff down into the flue. But the danger is not only from half-burnt stuff being carried down, but there is also another serious point, viz., that the fuel which is at the upper end of the furnace is of course being heated up by the flames in the furnace, and consequently giving off injurious and most objectionable gases at that comparatively low temperature, and instead of being burnt in the furnace they may be carried over into the flue immediately with the utmost facility, and become a source of great annoyance to the neighbourhood. In such a type of destructor there are always cases where objectionable and offensive fumes are perceptible, and not only objectionable smells, but unburnt material; consisting generally of a kind of scaly, shiny slag, in minute filaments, is seen to fall in the neighbourhood of the destructor, because this type of furnace does not allow of its being thoroughly burnt. I need hardly say that the higher the temperature in a furnace the better is the destruction of material, and not only is it desirable to have a high temperature, but also to have all the gas passing over that part of the furnace which has the highest temperature.

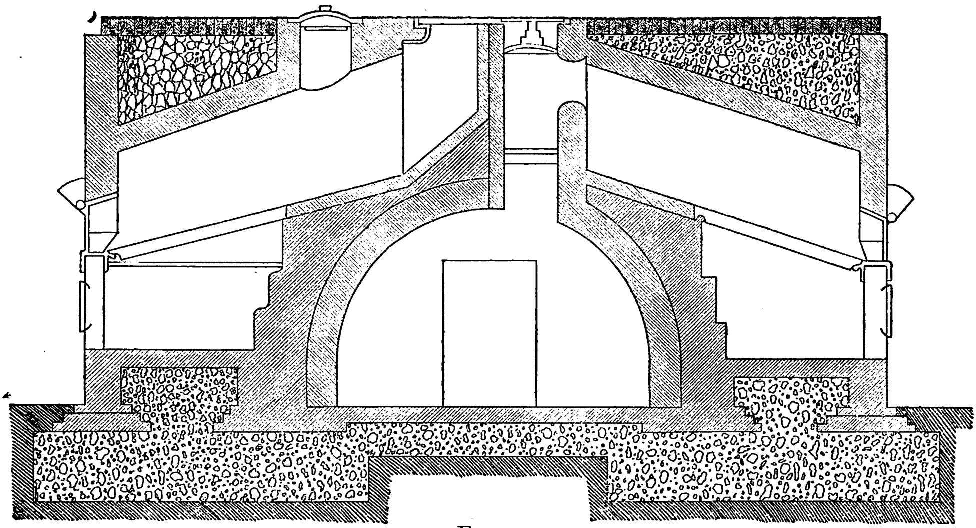

FIG. 1.

I might give a considerable amount of further instruction from the study of many destructors which have been put up, but I will only mention one appliance, which has been built to several destructors, and that is what is called a cremator. It was first introduced by Mr. Chas. Jones at Ealing. It consists of a furnace, in which coal is generally used, and over this furnace all the gases are passed before they go to the chimney, in order to burn the organic matter of the gases which have been allowed to pass through the furnace. I can only say about cremators—although I have seen a great many built—that they are very seldom to be seen at work, except when there is a deputation coming to examine them, because the cost of working them is far too great. If anything in the shape of a cremator were to be used at all, I would suggest that the gases ought to be passed a second time through the furnace, from under the fire bars. Since there is 80 per cent. of air in the gases that come out of the chimney, it is perfectly clear that we could get good combustion in a furnace, if those gases were fed under it.

I will now speak a few words about the best arrangement of destructors which I have ever seen up to the present time, and that is, one of the destructors which are used at Leeds. In 1878, the Corporation began, in an experimental way, with six cells at Burmantofts; in 1879, six more were put up at Armley-road; in 1882, four more cells at each of these places; in 1887, two more cells were put up at Armley-road, and in 1890 they built ten new cells at Kidacre-street. Thus you see Leeds has been

steadily progressing. The first work was purely experimental, but they were thoroughly satisfied with the experiments, and they proceeded to continue the same work. At every step they have seen some improvement which could be introduced, and even at this present moment in connection with what I have just spoken of as the best destructor in existence, they are just going to put down a new destructor, and are going to introduce some totally new improvements. Here again they are going to have experimental work, and see how it does, and if it succeeds, as I think there is little doubt it will, they will proceed to build destructors on the improved plan. In these old destructors some steam was got up to drive a mortar-mill, the clinker being used to make the mortar of, and a considerable amount have they been able to sell. This clinker is always a source of trouble; one-fourth of the weight of the fuel is given back in that form. You cannot be burning iron pots and crockery without getting a certain amount of slag from it; nevertheless, it is found to be the cheapest way simply to put the whole stuff in as it comes from the ash-pits, and burn everything, whether it is combustible or not, if I may use the expression. Consequently there is a large amount of slag, but this slag can be broken up and used for mortar, and it makes admirable mortar. It can also be used for road beds, road foundations, and ballasting, and when powdered and mixed with cement it can be made into artificial stones and paving slabs. The labour at each of these Leeds destructors is one foreman and engine driver, six furnace men, and one labourer. The whole place is perfectly clean, and kept in regular working order. Every pair of cells is charged every twenty-five minutes; they are banked at 1 p.m. on Saturday until midnight on Sunday. The damper to the boiler flue is closed at 7 p.m. on Saturdays. Everything is perfectly methodical. The fuel is carted in up an inclined road over a platform, and tipped upon the platform on the top of the destructor. In the diagram shown here of the Kidacre-street destructor (Fig. 2, p. 906), which I am able to give you through the kindness of the engineer, Mr. Hewson, who has let me have the actual plans which were used in the construction, you will see that half the section shows the furnace, and the other half shows the cell-flue, which is parallel to the furnace and intermediate between every two furnaces. You will recognise some resemblance to the Fryer destructor in this arrangement. The gases, however, before leaving the furnace, pass over the hottest part of the fire, and leave by a hole at the side of the furnace—marked cell-flue in the left-hand section, and also shown in the right-hand section—thence passing along one of the cell-flues into the champion flue, whence they pass on, it may be, by the boilers, it may be by a bye-pass to the chimney. This is the most important improvement that has been introduced by Mr. Hewson. Another great improvement on the old destructors is the addition of a forced draught. Instead of using a blowing engine, as they had plenty of steam in their boilers which they did not want to use in any other way, to avoid having a steam-engine to work, they have driven the steam directly through a jet and through a funnel-shaped aperture (shown underneath the fire bars), the jet of steam drawing air in through it, which passes through the fire bars, and produces a fierce draught, thereby giving very much greater heat, and enabling us to burn a very much greater quantity of material in a given time. I have given you another view here (Fig. 3, p. 907), showing the front elevation of the cells, and showing the general appearance of the place. Here you have the five furnaces which are on one side of the destructor, and there are other five behind these, and the cell-flues in the middle between. The steam coming from the boilers is led to the funnel-shaped inlets for the air, as shown. The fire bars are herring-bone shaped, and are capable of being rocked up and down by means of a handle, thus facilitating the disengagement of the clinker.

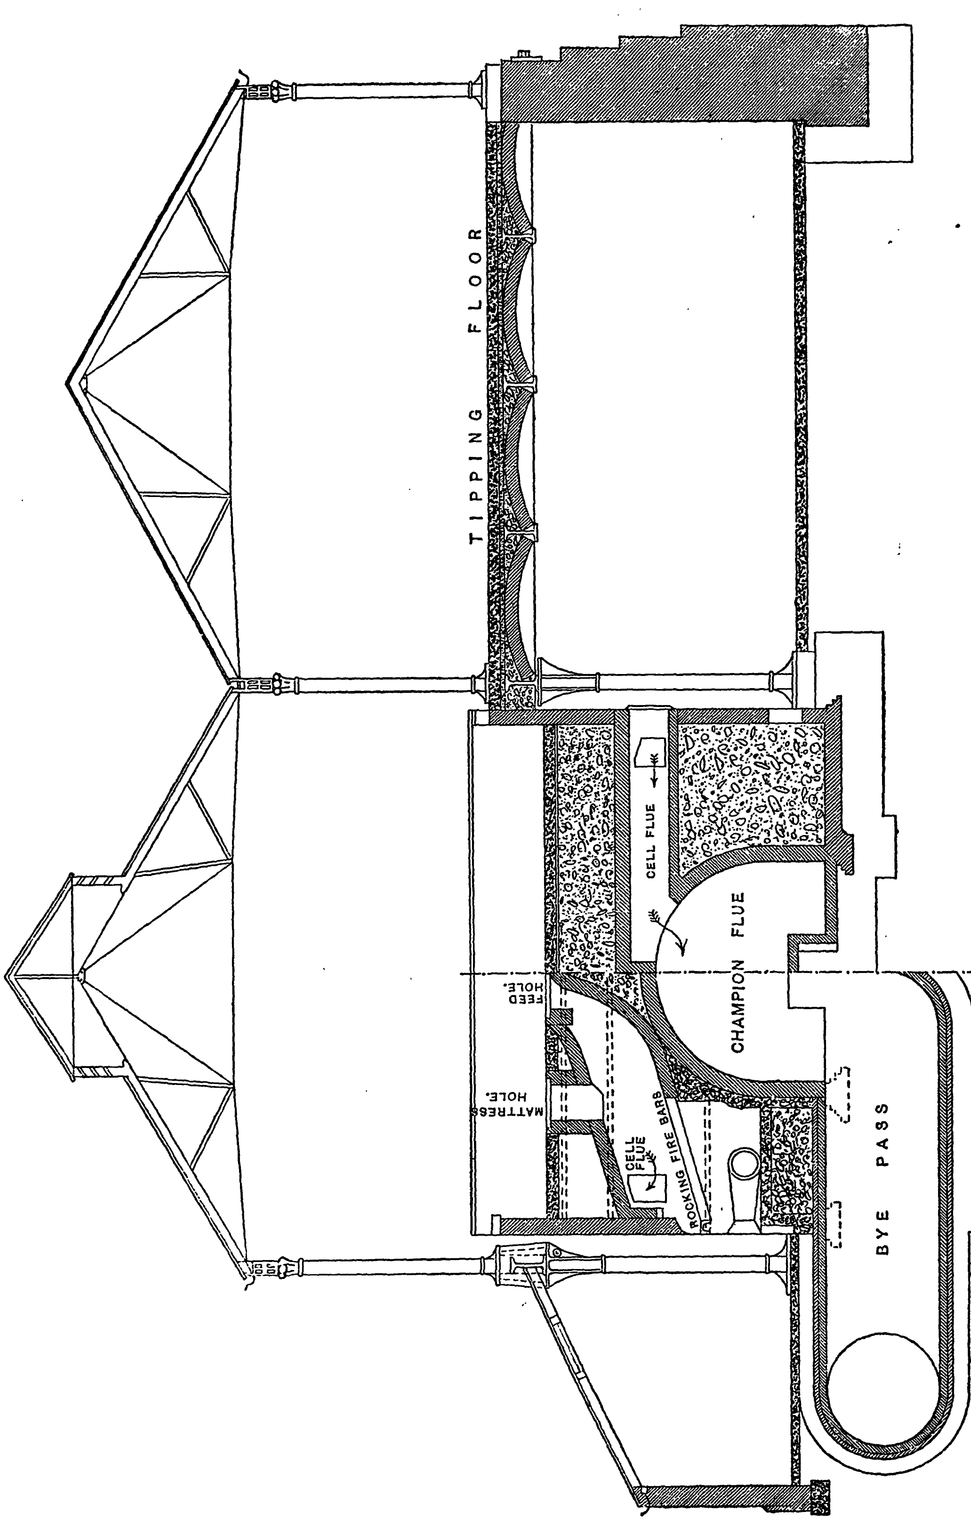
During a single year, up to 1886, that is before the new destructor was built at Leeds, there were 20 cells, which burnt 35,248 tons of refuse. We may generally assume that each furnace is capable of burning about 34 tons a week. The refuse contains ordinary ash-bin refuse along with trade and market refuse. Therefore, in addition to what I have mentioned as being found at Paddington, there was market refuse and other material of that sort, among which I may mention some totally different things. There were 11 cows burnt, 3 calves, 17 sheep, 4 goats, 298 pigs, 5 turkeys, 2 carcases of beef, 28 quarters of beef, 9 cwt. of pork, 10 cwt. of pickled tongues, 12 cwt. herrings, 218 cwt. shell fish, 1 cwt. sugar, 285 dogs, 109 cats, 13 foxes, 1 sea serpent, 147 mattresses, beds, pillows, and bolsters, 7 blankets, quilts, and sheets, 36 pieces of carpet, 7 hearth rugs and mats, 33 pieces of clothing, 1 bedstead, 1 sofa, 1 chair, 1 bundle of rags.

It is something to say that, without any complaint, the destructors at the high temperature at which they work were able to destroy all these objectionable things, which have been found so difficult to get rid of in any other way. The cost of working these furnaces for this one year before the new ones were introduced was:—For wages, £1,162; coal, oil, water, tallow, and gas, £181; implements and repairs, £227; rates, taxes, and insurance, £153; lime, for the mortar making, £78; total cost, £1,801; less mortar and old iron, which was sold, £395; leaving the total cost £1,406. Or, including interest, &c., a cost of 1s. 3d. a ton for destroying refuse. This is less than it would have cost to cart away the material and dump it, besides being, of course, far less objectionable, and the only healthy way of disposing of the refuse. The Leeds destructors, which are going to be put up in the immediate future, have several improvements in the matter of more area; in the matter of washing smoke, to get rid of dust and other objectionable particles that go up the chimney; and the most startling and most efficient idea of automatic feeding. Mr. Hewson tells me he has the intention of having the fire-bars formed in one continuous feeding belt, going along the whole range of the furnaces, the fuel being fed in at one end and carried along over one continuous furnace, being gradually burnt as it travels along. I am sure, judging by the success that Mr. Hewson has had in his past experiments with destructors, what he is going to do now will be very successful; and the smoke washing he has introduced is a plan which has proved to be the most successful mode of getting rid of smoke which has occurred to me.

Various tests have been made of destructors by pyrometers in Leeds. The temperature of the gases at the east end of the furnaces at Burmantofts was over 1,500° Fahr.; at the west end, between the furnaces and the chimney stack, 1,150°; at the bottom of the chimney stack, 875°; the furnaces being fed with air by an arrangement of steam jets, different to that in the new destructor, where they are considerably better arranged than has ever been the case before in the manner I have already described to you, the rapidity of burning being very much greater, and the temperature much higher. Dr. Spottiswoode Cameron, medical officer to the Corporation, has given me valuable information in connection with the destructors. He has gone into these questions of the temperature and analyses of the gases, and he tells me that his experience is that the temperature measured with the pyrometer is very much a function of the observer, but they have had most careful men for measuring these temperatures, and in the new destructor the pyrometers do not read over 1,500°; they are not capable of reading high enough temperatures to read the temperatures in this destructor, so that really during a great portion of the time the temperature is over 1,500°. Mr. Alderman Ward has given some details of some tests which were made with the steam jets, and without the steam jets in this new destructor. The effect was, that while the steam jets were not in action, the average temperature was 1,118°; while the steam jets were in action, the average measured was 1,464°, but in a number of cases the temperature was higher than the 1,500° registered, because the pyrometer would not register more, so that you may be sure that the real average was over 1,500°. Without the jets 6·2 tons were burnt in each cell per day; with the jets 6·7 tons per day. This is a marked improvement over the old experiments made in former times. Mr. Thomas Codrington, who made such an admirable report to the Local Government Board some years ago on furnaces, estimated the average temperature as follows for different places:—In the Whitechapel district, 180° to 1,000°, the average of eight cells being 490°. At Ealing he found 855°, 520°, and 520°. At Bradford, in the main flue, the temperature was 415°. So that there is no doubt that in the Leeds destructor we have a much more valuable result, and it only remains to arrange for generating the steam in a proper manner to get a really good result. The residuary gases have been tested at Burmantofts, and the proportion in every 100 parts is—of air 81·67, carbonic acid 4·0, carbonic oxide 0·16, nitrogen 14·17.

Now, I could have given you a great many more facts about destructors which would have been very interesting, but I think I have said enough to show you that they will play a most enormous part in the industrial lighting of the future, and, at any rate, that the concluding subject of this course of lectures which I have delivered you is one of the most promising lines for engineers to study and develop as far as in them lies.

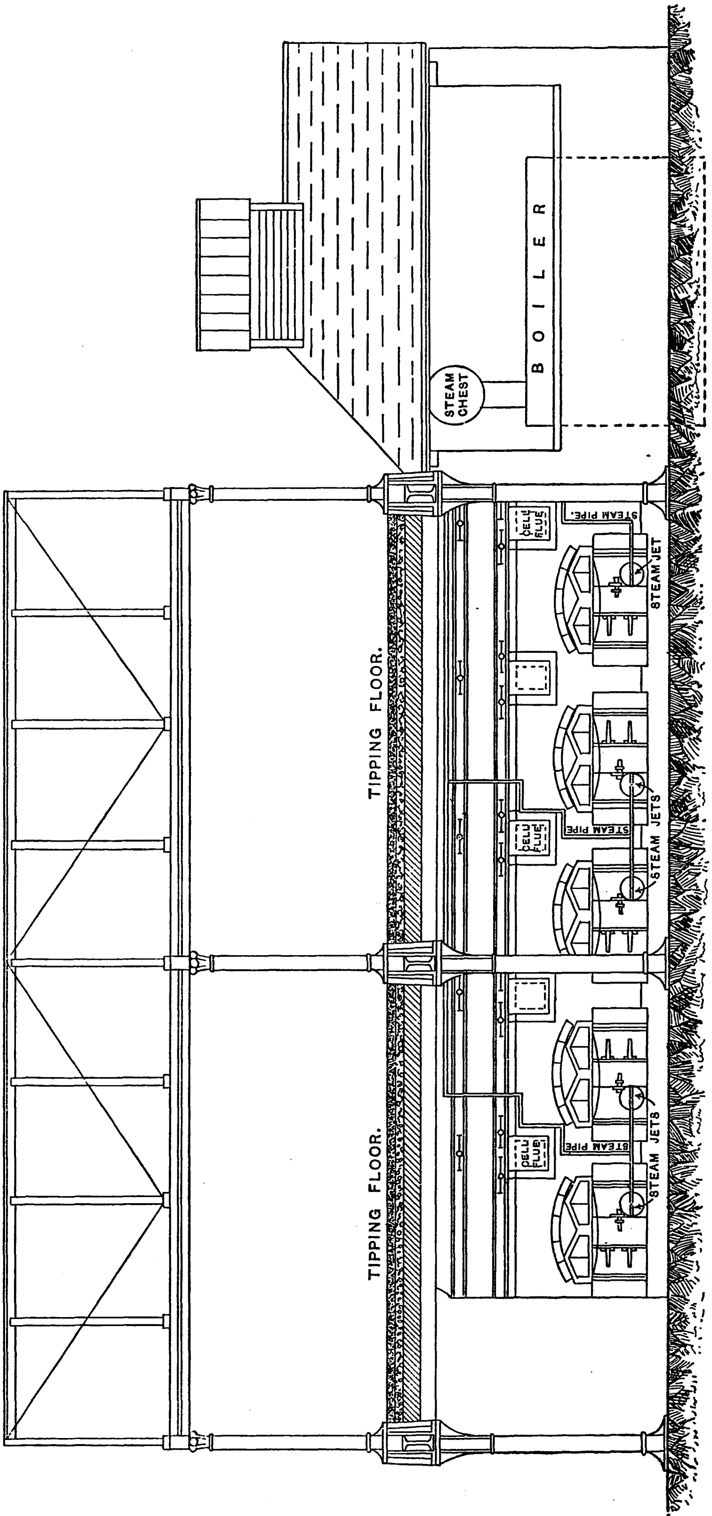
With regard to the other details of the lectures which I have drawn special attention to, I should just wish, in conclusion, to repeat to you one or two points to which I drew



Half Section between Cells.

Half Section through Cells.

FIG 2.



ELEVATION OF FRONT OF CELLS.

FIG. 3.

attention earlier. First, I wish to reiterate the fact that in large central station works on the alternating current system, the plan which must recommend itself to engineers of the present day is to depart from the old plan, and to use low tension secondary mains all over the district that is to be supplied; to have subsidiary stations with large transformers in them, with attendants to regulate them if necessary, or else automatic means of regulating them, so that we may have our machinery always at work at an efficient rate; and last, but by no means least, when we come to work in this way, and to put transformers into sub-stations, that probably the most efficient way will be to use alternations of much lower frequency than anything we have been dreaming of in the past; and for my own part I shall watch with interest to see what manufacturers will do when they see that this is the line on which work must be done. It will be interesting to see whether manufacturers will be ready to supply the machinery required for low frequency when that demand comes, as it undoubtedly must come in the immediate future. Low frequency is not only an advantage because large thick secondary mains can carry currents of low frequency efficiently, while they cannot carry currents of high frequency efficiently, but also because the currents of low frequency will be directly available for motors; and, although I prefer to have motors on a separate circuit, there is no objection to using light motors, never going over one horse-power or so, on the lighting circuits; and for that purpose the low frequency current will supply us with a solution of the problem immediately. We shall also be able to rectify the current, so as to use these slowly-alternating currents, for charging storage batteries, or to perform other electro-chemical operations. For all these purposes, I have no hesitation in saying that that is the best means of modifying the existing practice in connection with alternate current central station work.

With regard to continuous currents, and central station work at low pressures, all I have to say is, that although I cannot see at the present moment that actual economy is introduced by the employment of accumulators in central stations, still they have an enormous convenience, and, if they can be reduced in price, they will be largely used for taking up part of the work at slack times, and also for taking up part of the work during the maximum output. At present, I cannot see that there is any economy in these two things. It is cheaper to generate your current direct, by means of a steam-engine and dynamos, for these two purposes. But the value of accumulators is for regulating the pressure which you are to supply to your feeders; and so enormously important is it that something of that sort must always be used in central stations, that I have only to say that, in the operation, where you do not want to have a very large discharge of current for overcoming a breakdown in your machinery, if you are sufficiently satisfied with your machinery not to expect a breakdown, I would not use then the expensively made up accumulators. I would use nothing but simple plates of lead cut into a definite shape, without putting any oxide into them, or without any previous preparation of the lead, and without paying royalties for any patent rights. I would use the old Planté battery pure and simple, in the cheapest form in which it can be made.

I think these are the only points which I have mentioned in my lectures to which I wished to draw your particular attention, and I hope I may not find that I have made any mistake in drawing attention to these, as points which would deserve very great attention at the present moment.

General Notes.

BELGIAN TELEPHONE SYSTEM.—The State has considerably supplemented the work of the companies constructing and working various small lines, and using on all of th m the double wire (while the companies have mainly continued the single one). The material used is the phosphorus bronze of Montefiore. The subscription varies largely, from 250 fr. in a radius of 3 km. in Brussels and Antwerp, to 125 fr. in Louvain and Malines. One interesting feature of the Belgium lines is that they are all connected with the principal telegraph offices, so that subscribers can send to these, by telephone, any telegrams they wish sent, and similarly they can receive telephonically any telegrams addressed to them. A copy of the telegram is sent at the same time. The number of telegrams thus sent by telephone in 1889 was 371,000; in 1890 it grew to 440,000. To facilitate the development of telephonic relations the country is divided by Government into a number of circles, containing several towns provided with central offices communicating with each other by means of a double wire. Thus the inhabitants of a small town like Heyst are able to speak with Bruges, Blankenburgh, Ostend, Middlekerke, and Nieuport.—*Nature.*

FRIDAY, SEPTEMBER 16, 1892.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Chicago Exhibition, 1893.

DEDICATORY CEREMONIES.

The dates for these ceremonies are the 19th, 20th, and 21st October. The following programme for the final, or actual Dedication Day, has been issued by the Council of Administration and the Committee on Ceremonies :—

The National salute, at sunrise, October 21, will inaugurate the ceremonies of Dedication Day. The President of the United States, ex-Presidents, members of the Cabinet, members of the Supreme Court, members of the Senate and House of Representatives, distinguished foreign guests and Governors of the different States and territories, with their official staffs, will be escorted by a guard of honour, composed of troops of the United States army, detachments of the United States naval forces, and regiments from the various State and National Guards, to the Manufactures and Liberal Arts Building, in which the dedication ceremonies will be held.

At 12.30 o'clock in the afternoon, in this building, the dedicatory exercises will be conducted, under the direction of the Director-General, as master of the ceremonies, according to the following programme :—

1. "Columbian March," written for the occasion by Professor John K. Paine.
2. Prayer, by Bishop Charles H. Fowler, D.D., LL.D., of California.
3. Introductory address by the Director-General, as master of ceremonies.
4. Address of welcome and tender of freedom of the City of Chicago, by the Hon. Hempstead Washburne, Mayor.
5. Dedicatory ode; words by Miss Harriet Monroe, of Chicago, from which selections will be read; music by G. W. Chadwick, of Boston. This production is a tribute to woman's work, and introduced in recognition of the Board of Lady Managers.
6. Presentation of the master artists of the Exposition to the President of the World's Columbian Exposition by the Director-General of Works, and the award to them of appropriate medals, commemorative of their completed woik, by the President of the United States.
7. Chorus, "The Heavens are Telling."
8. Presentation of the buildings for dedication by the President of the World's Columbian Exposition to the President of the World's Columbian Commission.
9. Presentation of the buildings on behalf of the World's Columbian Commission by the President thereof to the President of the United States for dedication.
10. Dedication of the buildings by the President of the United States.
11. "Hallelujah Chorus," from "The Messiah" (Handel).
12. Dedicatory oration, the Hon. William C. P. Breckinridge, of Kentucky.
13. "Star Spangled Banner" and "Hail Columbia," with full chorus and orchestral accompaniment.
14. Columbian oration, the Hon. Chauncey M. Depew, of New York.
15. Chorus, "In Praise of God" (Beethoven).
16. Prayer, by the Most Rev. John Ireland, Archbishop of St. Paul.
17. Benediction, the Rev. Dr. McCook, of Philadelphia.
18. National salute.

In the evening a special electric and pyrotechnic display will be given on the Exposition grounds appropriate to the occasion.

LIVE STOCK EXHIBITION.

Since the publication of the Regulations relating to the Exhibition of Live Stock in the *Journal* for July 15th last (see *ante* p. 797), further arrangements have been made, and the following regulations have just been issued :—

The Exhibition will be held from June 12th to October 28th, 1893.

The dates for different divisions are as follows :—

A. Cattle, and B. Horses, Jacks, Jennets, and Mules ..	Aug. 21 to Sept. 21.
C. Sheep. D. Swine..	Sept. 25 to Oct. 14. (Entries close July 1.)

E. Dogs ....June 12 to 17.
(Entries close May 20.)

F. Poultry, Pigeons, and Pet Stock. G. Fat Stock .... } Oct. 16 to 28.
(Entries close in F., July 15, in G., August 1.)

In divisions A. B. C. D. G. only two entries are allowed in each section. Animals will be subject to the quarantine regulations, and must be on the ground by the opening day for division, but can be sent three days before.

Applications (to be made with the sanction of the Commission) must show, except in divisions E. F. G., as otherwise stated, 60 days ownership, name, age (to be computed up to September 11th for cattle; horses, August 24th; sheep and swine, October 2nd; dogs, June 12; fat stock, October 16), sex, description, and registration in one of the herd, stud, or stock books to be set out, or that the animal is of a recognised breed for which no established record exists. In the case of 5-year stallions and mares, and 4-year bulls and cows, or 3-year rams and ewes, and 2-year boars and sows, evidence will be required of siring or producing, within two years immediately preceding August 21 or September 25 respectively.

The Departmental Chief can form additional classes, exclude any animal not a typical representative, or remove any that are vicious or fractious. Accommodation will be provided, but the exhibitor must keep the same in proper order, and provide attendants. A veterinary surgeon will examine animals before admission, and inspect and report daily, and sick animals will be removed to a separate enclosure. Facilities will be provided for distribution of water, and forage, grain, and bedding will be furnished at reasonable prices from depôts within the grounds.

In divisions A. B. C. D. G. all animals will be placed in each section in order of relative superiority, and premiums paid in accordance with such numbering, *i.e.*, 1st, 2nd, 3rd, 4th (in the event of expulsion or disqualification after numbering, the subsequent numbers to be correspondingly advanced). The Jury may call for satisfactory proof, in writing, of any fact (save age, to be referred to a veterinary surgeon) required in connection with entry.

Protests must be in writing, and filed before the close of the period assigned to the division to which the protested animal belongs. In the event of death or injury of any animal (for which the Exposition will not be responsible), the chief of the department may authorise the substitution of another animal, in all respects eligible at date of original application. Right is reserved to add to, interpret, change, or amend the rules, as the interest of the Exposition may demand.

A. The premium list contains 14 classes of 15 sections each. Firsts, by age, single, $40 and $50; herd or collection, $75, $80, and $100; cow and two of her produce, $40 and $50; bull or cow, any age per class, medal and $50. Sweepstakes (6), herd: firsts, $350 and $500, and two of $200 and $350 each; and 27 by age, limited to 1st and 2nd prize winners, medal and $25.

B. The premium list contains 16 classes of 14 sections each. Firsts, by age single, $60, $75, $110, and $150; stallion or mare and colts, $150 and $200 (medal only in Morgans), and any age or collection per class, three medals; 2 of 14 sections, with medals and diplomas; 2 of 6 sections for horses to be shown under saddle and Shetland ponies, firsts, $110 and $100 respectively, and any age medals; and special class for mules, firsts, single $50, $100, pairs $150.

C. The premium list contains 13 sheep classes of 11 sections each. Firsts, by age single, $25 and $35, ram and ewes $30 and $40, pens $35 and $45, any age ram or ewe per class $50; and 2 goat classes of 7 sections each (only 1st and 2nd), firsts, by age single, $15 and $25, pens $30, any age buck or doe per class $40.

D. The premium list contains 9 classes of 8 sections each for single animals, 6 for collections. Firsts, former $20, $25, $40, and $50, latter $40 and $85; sweepstakes, boars or sows any age (4 per class), $35, $50, $75, and $100.

E. Entries must clearly identify the dog to be the *bonâ-fide* property of the exhibitor on or before May 1, giving date of birth, sire and dam, and name of breeder, and $1·50 must be remitted to cover cost of bench, feed, and care. Each dog must be passed upon by the veterinary before being benched. Juries (appeals from which will only be entertained where misrepresentation or breach of rules are charged) may disqualify any thought improperly tampered with, subject to veterinary's decision (if not sustained, class to be re-judged), and withhold prizes or medals for want of merit. Where weight is limited, the exhibitor, upon written request to departmental chief, can have weight of dog taken and registered. The premium list contains 42 classes, in 21 of which there is

a champion class, with medals. Firsts, \$20, \$24, \$30, and \$40; seconds, \$10, \$15, and \$20; thirds, diploma.

F. Poultry will be admitted under rules governing admission at competitions in England. Coops provided, and ·25¢ per bird to be paid for care and feeding. A committee will examine entries, and return sick or inferior birds.

G. The premium list contains for cattle 8 classes, 3 sections, first, \$35, second \$25, third \$10, and \$50 sweepstakes per class; sweepstakes, 3 of \$50, 1 of \$100; herds, 8 of \$50, 1 of \$200; for sheep, 11 classes, each 4 sections, first and second, firsts \$12 and \$17, and class sweepstakes, diploma; 2 sweepstakes of \$25 and diploma, and the grand sweepstakes \$75 and diploma; for swine, 10 classes, 4 sections, firsts and seconds, firsts \$20 and \$25; pen and breeders sweepstakes, firsts \$50 and \$75, seconds \$40 and \$50.

In addition to the foregoing, there are special premiums offered by associations and individuals.

WATER ROUTE TO CHICAGO.

The following information regarding waterways to Chicago will be interesting to any yacht-owner who may be contemplating a visit to the Exhibition next year:—

The route, *viâ* Canada, is up the St. Lawrence, ascending the river to Montreal. Then comes the Lachine system of canals, whose present capacity will not permit the transit of vessels of more than nine feet draught. The improvements on them—in progress—will not be completed before the conclusion of the World's Fair. The route from Montreal is through the Lachine Canal (8½ miles), five locks, depth of water on sills, 9 to 10 feet; Lake St. Louis (15⅝ miles); the Beauharnais Canal (11¼ miles), nine locks, depth of water, 9 feet; Lake St. Francis, (32⅝ miles); the Cornwall Canal (11½ miles), six locks, depth of water, 9 feet; Farran's Point Canal (three-quarters mile), one lock, depth of water, 9 feet; Rapids Flat Canal (4 miles), two locks, depth of water 9 feet; Gallop's Canal (7⅝ miles), three locks, depth of water, 9 feet; and, after Lake Ontario, the Welland Canal (27½ miles), 27 locks, depth of water, 14 feet, to Lake Erie. Thence, *viâ* Detroit River, Lake St. Clair, St. Clair River, Lake Huron, and Mackinac Straits to Lake Michigan, on which there is plain sailing in navigable waters to Chicago.

Vessels of greater draught have passed the canals by using pontoons and "camels." The Collins Bay Rafting and Forwarding Company, Collins Bay, Ontario, Canada, will furnish appliances and contract for the lifting of vessels through from Montreal to Lake Ontario and through the Welland Canal, if desired. The official tax for passage through the St. Lawrence and Welland Canals, from Montreal to Lake Erie, is 2¼ cents per ton register. This is levied upon yachts as well as other vessels.

Very full information as to methods of reaching Chicago by water was given in two articles which appeared in the *Field* newspaper, September 3rd and 10th. The first of these dealt with the Canadian route, the second with routes from New York *viâ* the Hudson River and Erie Canal, and from New Orleans *viâ* the Mississippi and Illinois rivers.

Proceedings of the Society.

CANTOR LECTURES.

RECENT CONTRIBUTIONS TO THE CHEMISTRY AND BACTERIOLOGY OF THE FERMENTATION INDUSTRIES.

By Percy F. Frankland,

Ph.D., B.Sc.(Lond.), F.R.S., Professor of Chemistry in St. Andrew's University, Dundee.

Lecture I.—Delivered May 2, 1892.

Although the fermentation industries are amongst the most ancient and venerable of all the arts and manufactures which have engaged the attention of the human race, they are precisely those which have had to wait longest before being placed on a sound scientific basis. Of incalculably greater antiquity than such industries as the manufacture of acid and alkali, of glass, or of artificial colours, all of these have undergone a much more rapid development as regards the perfecting of the processes involved, through the light of scientific knowledge, than has been the case in the fermentation industries, in which, until recently, many of the operations were shrouded almost in the same darkness that enveloped them thousands of years before the commencement of the Christian era.

The cause of this more tardy development is not far to seek; it is obviously due to the fact that, whilst the ordinary chemical industries depend upon chemical and physical changes in comparatively simple substances, the fermentation industries owe their existence to those far more subtle changes which are realisable through the intervention of what we now generally call "living protoplasm," which

was, until long after the beginning of this century, believed to be subject to entirely different laws from those governing the inanimate creation, and to be capable of bringing about changes through the mysterious agency known as "vital force."

But, although the first great wave of scientific discovery in the domain of organic chemistry, which marked the second quarter of the present century, succeeded in demolishing this phantom of Vital Force, by showing that substances which were only found in nature as the products of animal or vegetable life could also be produced artificially in the aboratory, yet, owing to the great complexity of most of these vital products, and the great experimental difficulties which generally attend their investigation, it is only natural that the progress of our knowledge concerning them should have been comparatively slow.

Thus, notwithstanding that one of the simplest—although most important—of these vital products, *urea*, was first artificially obtained already in the year 1832 by Wöhler, it is only within the last few years that even vital products of such comparative simplicity as the sugars have been artificially obtained by Emil Fischer, who has been assisted in their production by the practical experience and theoretical speculations of 50 years of unparalleled activity in every department of science.

It is sufficiently evident, therefore, that the accurate study of vital products is attended with great difficulties, and moves forward but slowly; and, on these grounds, we should anticipate that scientific progress in connection with the fermentation industries would be slow also. But there is a further difficulty attaching to their study, for the living organisms upon the vital activity of which these industries depend are so minute that their careful investigation has had to wait for the development of an elaborate technique which it has taken years and the ingenuity of numerous gifted experimenters to perfect. Thus microscopes of great power and special construction have had to be devised in order to render them distinctly visible, but owing to the only very slight differences in appearance which are exhibited by many of these minute organisms when viewed under the most powerful lenses, mere microscopic examination has proved quite inadequate to distinguish between them in most cases, so that supplementary study by culture, that is to say, by growing them in suitable media, has during recent years been more and more resorted to.

This study by culture, again, is attended with great difficulties, because, owing to the almost universal distribution of these minute organisms in all our surroundings, there is the continual danger of the forms we wish to study becoming mixed or contaminated with other forms accidentally introduced. Now, it is just in this direction of obtaining and maintaining what are known as pure cultures that such great strides have been made in recent years, and which have enabled the study of these minute forms of life to be prosecuted with accuracy and precision.

The operations connected with the study of these micro-organisms are of such a specialised character that this study may conveniently be regarded as a separate science in itself, to which we now generally give the name of bacteriology, although, of course, it really consists in the application of numerous sciences, such as physics, chemistry, botany, &c., to the study of the phenomena exhibited by these microscopic forms of life.

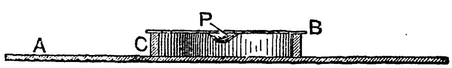
We will endeavour, in this first lecture, to make ourselves acquainted with some of the more important methods of study which have yielded such abundant fruit during recent years in all departments of bacteriology.

Microscopic Examination.

The older methods of examining a material for micro-organisms consisted in simply transferring some to a clean cover-glass, mixing, if necessary, with a little water, and then examining under a high power of the microscope. In this way the organisms can be seen in the living state, but owing to evaporation from the edge of the cover-glass, disturbing currents in the liquid are produced, whilst the whole soon becomes dried up, and further observation is thus rendered impossible.

In order to obviate these disadvantages, and especially to render observation in the natural and living state possible over hours, days, or even weeks, the device has been resorted to of cultivating in a suspended drop of nutritive liquid.

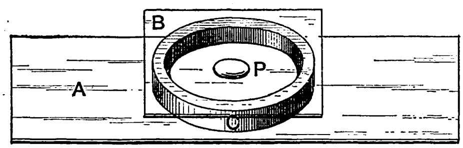
Fig. 1.



Suspended Drop Culture.

A Glass slide. B Cover glass. C Glass ring forming the wall of the chamber. P Drop of nourishing material in which the micro-organisms grow.

FIG. 1A.



SUSPENDED DROP CULTURE.

A Glass slide. B Cover glass. C Glass ring forming the wall of the chamber. P Drop of nourishing material in which the micro-organisms grow (after Klein).

In this manner the complete life-history of a micro-organism, from its cradle to the grave, can be watched. Seen under these circumstances some micro-organisms are found to be possessed of mobility whilst others are stationary. Again in this way the marvellous rapidity

FIG. 2.

BACILLUS SUBTILIS, SHOWING TRANSVERSE DIVISION. (After Klein).

of multiplication exhibited by some micro-organisms has been determined; thus in the case of one bacillus it has been found that division into two takes place in as little as 20 minutes.

STAINING OF BACTERIA.

The great advances which have been made in our knowledge of micro-organisms within recent years are largely due to the methods which have been devised for accentuating their appearance by means of brilliant colours. Striking colours are employed by both the savage and the civilised man, or rather woman, to render themselves more conspicuous, in the latter case by clothing in coloured garments, whilst by the savage the process of brilliantly colouring the body itself is adopted. Now this is also the process employed by bacteriologists to render micro-organisms conspicuous amongst their surroundings. The bodies of these micro-organisms are dyed, and the dyeing is carried out on the same principles as the dyeing of a skein of silk or a hank of wool.

These textile fibres, silk and wool, as is well known to dyers, are most readily coloured by what are called the basic colouring matters, to which group belong the brilliant aniline dyes, like magenta, methyl violet, malachite green, &c. The great advantage of these dyes consists in the rapidity and intensity with which they colour the materials for which they have an affinity.

It must not be supposed that all materials have an affinity for or can be dyed by these basic aniline colours, and the following experiment will serve to show how their affinity for the substances of which micro-organisms are composed enables these to be distinguished amongst their surroundings.

[Experiment.—Dyeing of silk and wool, which have been stitched through piece of calico, by immersion in dilute solution of magenta; on subsequent washing with water, the colour is removed from the calico (cotton), whilst the silk and wool remain permanently coloured.]

In most cases, however, the staining of micro-organisms is not such a simple matter as this, for the bodies with which they are surrounded have also generally a strong affinity for these basic colours, which results in these bodies becoming also dyed with the colour employed.

There is, however, a peculiarity about these micro-organisms which enables us to strongly dye them whilst leaving the surrounding matters colourless or only faintly tinged. The micro-organisms in fact appear to be invested with an envelope which offers great obstacles to the penetration of the colouring matter to their interior. This envelope of the micro-organisms, however, serves to protect them from influences which readily affect bodies not so surrounded, and it is this circumstance which is taken advantage of in various ways in the dyeing or staining of micro-organisms. Thus one of the simplest and most commonly practised expedients consists in exposing the micro-organisms and the materials with which they are mixed to such a temperature that whilst the other materials are so scorched by the heat that they are no longer capable of being dyed, the micro-organisms wrapped in their protecting blanket, so to speak, suffer, prac-

tically, no injury. On now applying the dye to the scorched specimen, the micro-organisms become strongly and permanently coloured, whilst the surrounding matters remain colourless.

You might think that it was very difficult to apply heat so delicately adjusted as to injure these other materials without affecting the micro-organisms, but as a matter of fact, with a little experience it can be done with great readiness and facility.

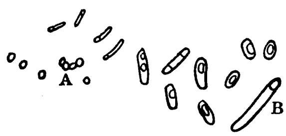
[Demonstration of preparation of scorched cover-glass with subsequent dyeing.]

In this manner, or by subsequently removing the dye from the surrounding materials by means of acids, the most beautiful microscopic preparations of micro-organisms can be obtained. Some idea of the appearance of these I can convey to you by means of the following coloured slides and diagrams.

[Demonstration of slides and diagrams of stained micro-organisms:—Spirilla of Asiatic cholera, typhoid bacilli, micrococci of erysipelas, yeast, &c.]

The examination of the stained micro-organisms, dyed as I have described, sometimes reveals the presence within the micro-organisms of small round or oval bodies which have not taken up the colouring matter. These bodies, shown in the following figures,

FIG. 3.



A.—SPORES MAGNIFIED 700 TIMES.
B.—SPORES AND BACILLI CONTAINING SPORES MAGNIFIED 1,650 TIMES.

are the so-called spores, which in consequence of their great power of resisting destruction are of such tremendous importance in the propagation of some micro-organisms.

Although sufficiently conspicuous by the fact of their not sharing in the gay colours which have been bestowed on the micro-organisms themselves, bacteriological artists are, nevertheless, fond of painting them also, which can be done by a little modification of the process I have described. To this end the preparation containing spores is dyed not with an aqueous solution of one of the basic colouring matters, but with a solution of the colouring matter in aniline water, which gives the dye a greater power of penetration. In this manner even the spores become dyed, and *à fortiori* the fully developed micro-organisms also. The colouring matter having penetrated into the interior of the spores, is there much more firmly fixed than elsewhere in the preparation, so that if we now submit the latter to a decolourising process by a submersion in dilute nitric acid (1 : 3), the colour will be last removed from the spores.

[Demonstration of decoloration of magenta by dilute nitric acid (1 : 10)].

Having then removed the colour by means of dilute acid from everything excepting the spores, we proceed to re-dye the fully developed micro-organisms by means of another colour in the ordinary way. In this manner a beautiful and most effective microscopic preparation is obtained, in which the spores are tinted with one colour, and the fully developed organisms with another, as in the following slide:—

[Demonstration of *Bacillus subtilis*, with spores stained in one colour and the bacilli in another.]

It is a highly remarkable phenomenon, that some fully formed micro-organisms offer the same difficulties in the way of being stained as do the spores. This is notably the case with one of the most important of all the micro-organisms with which we are acquainted, viz., the tubercle bacillus. The great value of detecting this bacillus for clinical purposes has led to a number of methods being devised for rendering them apparent through staining. These methods are based on essentially the same principles as those which I have described for the staining of spores.

[Demonstration of slide of tubercle bacilli in giant cell, the bacilli stained with methylene blue, the nuclei of the giant cell with Bismark brown.]

The refinements of microscopic *technique*, in connection with micro-organisms, have, however, gone even beyond what I have yet described; for none of the methods of staining already mentioned are successful in displaying certain highly important structures possessed by some forms, viz., the organs of locomotion, by means of which some, at least, of the motile microbes are able to propel themselves about in liquid media, often with fabulous rapidity. These organs of locomotion, unlike either the bodies or the spores of micro-organisms, have no affinity for these aniline colours, which we have seen are so useful in exhibiting the latter. In the practice of dyeing textile fibres we are also acquainted with

fibres which exhibit the same indifference to these colours; thus, cotton and linen cannot be directly dyed with the basic aniline colours, and, in order to dye them with these colours, we have, in the first instance, to prepare these fibres, by impregnating them with what are known as mordants.

[Experiment.—Cotton not dyed by solution of magenta, but cotton previously mordanted with tannin, takes the dye readily and permanently.]

Now, this is essentially the principle on which it has been found possible to demonstrate in the most beautiful way the existence of organs of locomotion in the case of motile micro-organisms.

FIG. 4.

TYPHOID BACILLI, SHOWING THE FLAGELLA, OR ORGANS OF LOCOMOTION. (After Migula.)

It will thus be seen that we are now provided with numerous appliances for carefully studying the form of micro-organisms. Indeed, with the best modern microscopes, and by carefully staining, their outlines are so sharply distinguishable, that the most beautiful photographic representations of these minute forms of life are obtainable.

CULTIVATION OF MICRO-ORGANISMS.

Although great strides have been made in the methods of examining micro-organisms microscopically, these improvements are really of far less importance than those which have been introduced in the study of these organisms by growth, or culture, as it is termed.

The cultivation of micro-organisms has become a matter of such many-sided interest and consequence, that it is impossible to discuss any questions connected with fermentation and other processes in which micro-organisms are concerned without a knowledge of the principal methods which are employed in their cultivation. We shall, therefore, be obliged to speak of these in some detail.

For the cultivation of all micro-organisms, more or less moist materials are necessary, both liquids and solids being employed for the purpose. It might be supposed that it would be easy to find a medium which would suit the requirements of all micro-organisms, since, from some points of view, they are all so similar; but, as a matter of fact, there is the greatest diversity in their tastes, and media which are suitable for the growth of some are utterly unfitted for the cultivation of others. Thus, whilst some organisms are unable to thrive and multiply excepting when surrounded with the most nutritious and subtle foodstuffs, others absolutely refuse to grow unless bathed in a liquid from which such organic materials have been most carefully banished. The ingenuity of the bacteriologist is, in fact, severely tried in endeavouring to cater for the organisms which he has under his charge, and every year, or even month, sees many additions to the *menu* from which he has to select, and which already includes such a medley as living animals, blood serum, bouillon, beef jelly, agar-agar, potatoes, bread, malt-wort, numerous purely mineral solutions, &c.

Whatever medium we may be employing, it is, before all things, necessary that it should be deprived of every form of living matter, so that only those organisms which we purposely introduce may be nourished and fostered. In the language of bacteriologists, the medium must be sterilised. This sterilisation may be effected in various ways.

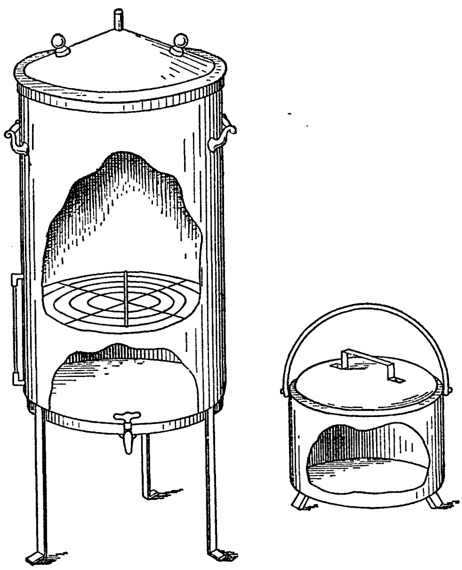
1. The medium may be naturally sterile or devoid of living matter, and in this case we have only to prevent the accidental introduction of living germs during manipulation. This is notably the case with blood serum; the blood of healthy animals is free from micro-organisms, and if, before inflicting a wound, the surface of the body be disinfected, and the blood carefully collected in sterile vessels, it will remain sterile, and the serum which separates can be further transferred to sterile vessels, which, if adequately protected from the access of living germs, will remain sterile and unchanged for an indefinite period of time.

2. More commonly we employ the agency of heat to effect the destruction of the living organisms which may be accidentally present in our culture-media; the most convenient mode of applying the heat being by means of steam, as can be done in the piece of apparatus represented in Fig. 5, p. 916, and which is generally termed a steam steriliser.

In order that this steaming may be certainly effectual, it is necessary that it should be continued for from half to one hour, which would seriously impair the qualities of some of the culture-media we employ.

This difficulty is overcome by means of what is called discontinuous or fractional sterilisation. It is found, in fact, that if a medium is repeatedly steamed on several days for a few minutes each day, it is as effectually sterilised as if it had been continuously steamed on one occasion for a long period of time. This phenomenon is generally explained on the assumption that the few minutes' steaming kills all organisms excepting spores, and that by allowing a day to intervene between the first steaming and the second, an opportunity is given to these spores to germinate, so that at the second steaming the fully developed organisms, to which the spores have thus given rise, will be killed also. A third steaming is

FIG. 5.



STEAM STERILISER

generally superadded to insure the process of destruction being completed. It is, however, in my opinion, far more probable that the effectiveness of the discontinuous application of heat depends upon the destructive action of the temperature being rapidly raised to the boiling point, and that the repeated raising of the temperature is far more fatal than if the high temperature is merely maintained over the same period of time. This discontinuous steaming is particularly necessary for the sterilisation of nutritive media containing gelatine, as prolonged steaming greatly reduces the melting point of the gelatine.

3. Discontinuous or fractional heating may be made a means of effectual sterilisation, even without employing a temperature as high as that of boiling water. Thus milk should be sterilised by heating it on four or five successive days for one hour on each day to 65-70° C. or 150-160° F., for in so doing the chemical character of the milk is not changed, as at this temperature the albumen is not coagulated as would be the case if it were heated above 75° C. or 167° F. This fractional sterilisation, which was originally devised by Tyndall, is one of the most important points in practical bacteriology.

The importance of the sterilisation of milk has become so manifest, that on the Continent it is now sometimes actually carried out on an industrial scale, and numerous forms of apparatus have been devised for effecting it.

The difficulty of preserving milk is equally felt by both dairyman and consumer; and the former frequently resorts to chemical additions of a very doubtful character to secure this end. The additions most commonly made are carbonate of soda and borax, the former having the effect of neutralising the lactic acid, which causes the souring and curdling of milk, whilst the borax exerts an antiseptic action, and thus prevents the growth and multiplication of micro-organisms, which bring about changes in the milk.

Far preferable is the preservation of milk through heat, for in this way also pathogenic organisms, which are liable to be present at any time in this excellent culture medium, are also destroyed. In Germany this industrial sterilisation of milk has been carried on for some years, by means of Thiel's apparatus, in which the milk is passed over a heated corrugated metallic surface which rapidly raises its temperature to 75-85° C., after which it is promptly cooled down to 10-12° C., by means of a refrigerator. More recently, Soxhlet has devised a method of preparing milk—more especially for infants—by heating in separate flasks to upwards of 75° C.; the flasks are then tightly corked, the heat being maintained a little longer, after which they are cooled. The milk thus treated is not necessarily or generally sterilised, for milk often contains just those microbes which are most difficult to destroy, and which have gained access from hay dust or the like. Owing, however, to the greater number of the microbes having been killed, it keeps better, and, most important of all, the pathogenic organisms will have been destroyed with almost perfect certainty. The importance of this latter point is sufficiently evident, without considering the

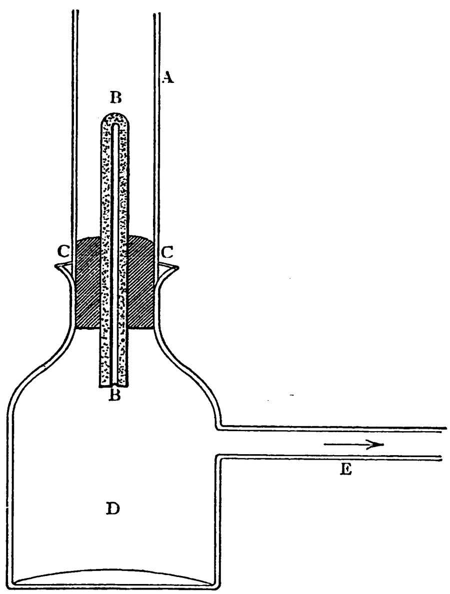
occasional communication of the ordinary zymotic diseases through milk, when we bear in mind the frequency of tuberculosis amongst cows. Thus, in the slaughterhouses of Silesia, it has been found that the following proportions of the cattle are affected by tuberculosis :—

Calves	·13	per cent.
Bulls	1·00	,,
Young beasts	1·87	,,
Oxen	7·31	,,
Cows	9·54	,,

Although it is highly desirable that such a sterilised milk industry should be established in this country, it is undoubtedly a still more satisfactory safeguard for the consumer himself to submit the milk to boiling before use.

4. After this digression we pass to another method of sterilisation, which has recently become of very great service where the application of heat is inadmissible, and which consists in filtration through porous porcelain under pressure, as shown in the following figure :—

FIG. 6.



PORCELAIN OR CHAMBERLAND FILTER.

A Glass cylinder in which the liquid to be filtered is placed. BB Porous porcelain hollow cylinder, passing tightly through india-rubber stopper (CC), which also fits the strong glass bottle (D) into which the filtrate passes, and in which a partial vacuum can be produced by connecting the side-tube (E) with a pump.

This method is of course only available in the case of liquids, and is of special value in the investigation of the products generated by micro-organisms, in which it is desired to separate the products from the organisms, as many of these products are destroyed or altered by high temperatures.

It is by the use of this arrangement that the various soluble ferments frequently generated by micro-organisms have been isolated, and it has been of special service in separating pathogenic organisms from the soluble toxic substances to which they often give rise during their growth.

Miscellaneous.

THE ELIHU THOMSON PRIZE.

At the last prize contest instituted by the City of Paris for the best electric meter, the prize of 5,000 francs was awarded to Prof. Elihu Thomson. With the desire that this sum should serve for the development of the theoretical knowledge of electricity, he has arranged that it shall be devoted to form a prize for the best work on a theoretical question in electricity.

The following gentlemen have undertaken to act as members of a committee to award the prize :— J. Carpentier, President of the Société International des Electriciens; Hippolyte Fontaine, Professor E. Hospitalier, E. Mascart, A. Potier, B. Abdank-Abakanowicz, Secretary.

The committee has decided that the prize should be given for an investigation on one of the following subjects :—

1. The heat developed by successive charges and discharges of condensers under different conditions of frequency, nature of dielectric, and quantity of charge.

2. It has been shown, theoretically, that when the two surfaces of a condenser are connected by a conducting body, the condenser becomes the source of alternating currents, as soon as the resistance of the conducting body decreases below a certain limit. The formula that permits calculating the period of this oscillation has not yet been completely verified. This period of oscillation should be investigated experimentally, under such conditions that the exact measure of resistance, capacity, and co-efficients of self-induction may be possible, in order to arrive at a complete and precise verification of this formula.

3. When a condenser, made with an imperfect insulating material, has been charged, and then left to itself, the charge is gradually dissipated. The time necessary for the charge to be reduced to a given fraction of its initial value depends only on the nature of the insulating material. It is proposed to investigate whether, as certain recent theories would seem to indicate, analogous phenomena do not

present themselves in metallic conductors, and whether these can be shown experimentally.

4. It is proposed to arrange and systematise our present knowledge of the graphical solutions of electrical problems, and deduce from them some general methods, as in graphical statics.

The essays presented may be written in any one of the following languages:—English, French, German, Italian, Spanish, or Latin. They may be in manuscript or printed.

Each essay must be signed by a pseudonym, and accompanied by a sealed envelope bearing the same pseudonym on the outside, and with the name and address of the author inside.

The papers must be sent before the 15th September, 1893, to B. Abdank-Abakanowicz, Consulting Engineer, the Secretary of the Committee, at 7, Rue du Louvre, Paris, who will furnish any further information required.

THE TRADE OF CHICAGO.

In his last Consular Report on Trade and Commerce of Chicago for 1891, Colonel Sadler furnishes much information likely to be of value to those interested in the Chicago Exhibition, either as exhibitors or visitors.

The record for 1891 shows continued increase in trade and commerce, and the bulk of business has exceeded that of any previous period, the past season being distinguished by the largest return of cereals ever produced in this region. The total trade of Chicago in 1891 is estimated at £300,825,000, against £284,500,000 in the preceding year, or a little less than one-third of the total bank clearings. This includes the produce, wholesale, and manufacturing trades, only such transactions in produce as have been followed by delivery from producer to consumer, and is calculated on the first selling value of all goods arrived, except the precious metals, with the additional value that they may have acquired by local manufacture. The great increase of $17\frac{1}{2}$ per cent. made in the volume of trade in 1890 has been maintained, and a further increase of about 5·7 per cent. has been made. The principal feature of the produce trade was the large increase in the receipts and shipments of wheat. Rye arrived in larger quantities, while there was a falling-off in corn and barley. There was a large decrease in the receipts of cured meat and lard. Prices were not subject to many fluctuations, and average prices were much the same as in the preceding year. Live stock receipts exceeded those of any previous period; provision trade active; stock of cheese, of which autumn product short, exhausted by foreign demand; hay ruled unusually high; fruit crop abundant, and, though prices consequently low, value of receipts exceeded that of preceding year, when crop was short and prices high.

The wholesale trade of 1891 shows in business done a fair advance over the preceding year, the excellent harvest having enabled increased purchases to be made. In many articles the value has not been greater, though a greater volume has been handled, especially in the wholesale grocery trade, in some articles of which the prices realised were far lower than in 1890. Prosperity, however, ruled throughout. The great activity in the building trade caused an unusual demand for all material consumed in construction. In structural iron and in brick and tile an advance of 10 per cent. is reported, but a smaller quantity of the finer tiles are imported than formerly. In the dry goods business is noticed a large increase in demand for goods of American production, and a corresponding reduction in the sale of foreign goods of superior quality, resulting from the higher tariff. The larger houses may import as much as before the new tariff, but the smaller retailers are said not to have found it profitable to import as many articles of foreign manufacture, the disposal of such goods at the higher figure which duties necessitate being less easy, and some goods, such as underclothing, carpets, and other articles of home production and inferior make, are supplanting the imported article of finer quality. A very large quantity of goods were, however, imported in anticipation of the tariff, and no positive opinion can yet be formed of the effect of the tariff. In jewellery there has been an estimated increase of 20 per cent. In lumber the demand is greater than the supply.

Manufactures were somewhat depressed at the commencement of the year from overstock and monetary depression. The large increase in production in 1890 of $19\frac{1}{2}$ per cent. over that of 1889, has, however, been maintained, and a further increase of $5\frac{1}{2}$ per cent. is estimated. Chicago is yearly becoming more independent of foreign imports, and extending the market for its manufactur[illegible]e wages paid increased from £19,837,000 to £21,588,000, the estimated value of product from £110,928,000 to £116,910,000, the capital employed from £39,175,000 to £43,361,000, and the number of workmen from 177,000 to 180,870. The packing business, the most important industry, including the manufacture of butterine (in which a considerable increase took place), and other products shows a slight falling off. In the iron and steel industry the capital employed and total output increased, though fewer men employed. The metal industries turned out less with increased capital. The McKinley Act has raised the cost of cans, but a large surplus stock was imported in anticipation and no rise has yet taken place in packed goods. In the iron and wood industries there was a falling off in value of product, though capital employed increased. In manufactures of wood value of product slightly increased. Of late the number of musical instruments made has greatly increased. For bricks the price averaged low with a good demand. Scarcely any tile, or terra-cotta, or stained glass is now imported, the domestic product of somewhat inferior quality

being preferred, as the cost is less. In all the above industries, though much more capital is invested, the returns have been generally less, prices having been depressed greatly owing to more competition. Fourteen new breweries were started last year, and there are 814 distillers and rectifiers. In chemicals there is an increase of 20 per cent. in production, and 30 per cent. in cost of labour.

The imports in 1891, though £57,964 less than in 1890, exceeded in value those of 1889 by £331,635. The increase in value of free goods, however, compared with 1889, amounted to £176,225, so that the value of dutiable goods imported in 1891 increased only by £165,410 in the two years; and, not counting free goods, the imports on dutiable goods in 1891 were only £38,325 less in value than those of 1890, and amounted to £2,434,171. The amount of duties levied increased by £169,652 from 1889 to 1891, so that the result of this comparison would be that, since 1889, free goods, dutiable goods, and customs' duties have each increased by £170,000. The condition in 1890 was abnormal, on account of the quantity of goods imported, in anticipation of the McKinley tariff, and probably some of this extra stock was not worked off till the early months of 1891. And again, comparing the imports of 1891 with 1889, and not forgetting the greatly increased trade of the city, the commodities which appear to be most affected by the tariff, and of which the import has decreased, are art materials, cigars, cutlery, diamonds, and precious stones, drug sundries, dry goods, guns, leather goods, needles, plate window glass, and toys and fancy articles. Caustic soda, dried fruits, paintings and statuary, have also been imported in smaller quantities. The cigar and tobacco trade has been revolutionised, and a great impetus given to home manufacture. In dry goods, on account of diminution in the imports, and the greater cost of the foreign product, articles of domestic manufacture have been in much demand. Diamonds and precious stones have decreased almost two-thirds in value. Guns have been greatly affected, and needles have almost disappeared as an import. But china and glassware, dressed furs, iron manufactures, jewellery, looking-glass plates, metal manufacture, paper, smokers' articles, wines, and wood manufactures have largely increased in import, while the value of some other articles imported has increased, and amongst them that of tin-plate. As yet the output of the tin-plate manufactories which have started here scarcely supplies 1 per cent. of the ever-increasing consumption. The exports by lake to Canada, consisting almost entirely of flour, wheat, corn, rye, were more than double. Those of domestic produce to Europe on through bills of lading, consisting chiefly of flour, wheat, corn, clover, and other seeds, fresh beef, lard, cheese, and oil-cake were also large. Competition reduced the value of oil mill products by nearly 50 per cent. The 87 leather businesses increased their capital, but the product was about the same.

Textile industries, including clothing of all sorts, show an enormous increase in the value of production, being stated to have turned out to the amount of £10,825,000, against £7,902,000 in 1890. This is partly the result of larger purchases owing to the bountiful harvest, and partly to the higher duties on foreign goods. The McKinley tariff has raised prices all round. Fewer articles of foreign manufacture were imported, and the cost of such goods is greatly higher. Some of the large houses import as much, or nearly so, as before the tariff came in force; but some of the smaller retailers are said to have given up importing any foreign goods, the cost being such as to make them unmarketable or not easily disposed of, and find the inferior article of domestic manufacture has a readier sale. The consequence has been an increased demand for goods of home manufacture, and a consequent rise in prices, the consumer being now forced to give more for an inferior article. The printing, publishing, and newspaper industries show an increased total output. The demand for bicycles is being almost wholly confined to local manufacture, which is considered quite equal in every way. The return at the Port of Chicago for 1891 gives a total of 20,618 vessels entered and cleared.

MANUFACTURE OF FLOOR MATTING IN JAPAN.

Her Majesty's Consul at Hiogo, in his last report, says it is satisfactory to find that the importance of the floor matting industry has nearly doubled during the past year, and there is every reason to believe that the demand from foreign countries is largely in excess of the present production. The plant from which the matting for export is made also supplies the mats universally used for the same purpose by the Japanese, and the chief producing districts are situated in the provinces of Bizen, Bitchin, and Bingo, on the borders of the inland sea, and Bungo and Chikugo in Kinshin. The seed is planted in December, and the crop is gathered in June and July; the manufacture from the new grass, commencing in August, continues actively until early in the following year, during which interval the chief shipments are made. An interesting feature in the making of this matting is the introduction of a warp of cotton threads, numbering, in the finest qualities, some 360 to the yard, thus producing a fabric which is almost as soft and pliable as cloth; in the cheaper kinds, however, native-grown hemp is used for this purpose, and the difference in the finish is at once apparent. The machines on which the matting is made are all of home manufacture, and of rather complicated and ingenious construction; they are worked by the foot of the operator, two or three persons being required for each machine. Aniline dyes are used in colouring, and such is the skill with which this work is done, that there is seldom the slightest variation in shade in any number of rolls in

the same order. The beauty and variety of the designs offered to the foreign purchaser is somewhat surprising, considering that the trade may still be considered to be in its infancy, one foreign firm having stated that they sent away over four thousand different patterns. The Japanese are so clever and industrious in work of this description that they have, it is said, before them the prospect of a very large and profitable trade, with little fear of injurious competition from Canton matting, which is altogether a different article. Prices for a roll of forty yards in length by one yard wide vary, according to quality and workmanship, from 3 dols. to 15 dols., the principal demand being for qualities costing from 6 to 10 dols. The rolls vary in weight from 35 to 100 lbs. each. The United States are by far the best customers at present, but shipments to the Australian market are becoming more and more important, and Consul Enslie says that before long Japanese matting will probably be in demand all over the world. The value of the export of this article, which was only £86 in 1886, rose, in 1889, to £25,389, and amounted to £104,369 in 1891.

Notes on Books.

YEAR-BOOK OF THE IMPERIAL INSTITUTE. First Issue. 1892.

This first issue of what will doubtless be an annual publication is intended as one step towards the "collection and diffusion of the fullest information in regard to the industrial and material condition of the colonies," which is stated to be one of the principal objects of the Institute.

The conception of the book is accredited to Sir Somers Vine, the assistant-secretary of the Institute, the completion of its scheme to Sir Frederick Abel, the secretary, and its execution to Mr. Fitzgerald, the librarian. The book is intended to deal with the physical geography, the natural resources, and the industries and commerce of the colonies and India. It commences with a brief sketch of the trade of the United Kingdom, showing in tabular form the variations in the imports and exports of each main article of commerce during the past five years, and the countries which export and import them.

The pages devoted to each colony contains a brief historical sketch, an account of its physical features, and details of its trade, population, &c. There are no maps, but in many cases full-page diagrams are given, showing the course of trade during a period of years.

General Notes.

ELECTRICAL STANDARDS.—At the recent meeting of the British Association, Mr. R. T. Glazebrook, F.R.S., presented the report of the Committee on Electrical Standards. The earlier part of the report dealt with the testing of resistance coils, and also of Clark cells. The cells set up by different persons at different places and times gave almost identical values for their electromotive force, thus proving the adaptability of this cell as a standard one. During the year the committee had passed the following resolutions, with a view to their adoption internationally:—"(1) That the resistance of a specified column of mercury be adopted as the practical unit of resistance; (2) that 14·4521 grammes of mercury, in the form of a column of mercury 106·3 c.m. long. at 0 deg. C., be the specified column; (3) that standards in mercury or solid metal, having the same resistance as this column, be made, and deposited as standards of resistance for industrial purposes; (4) that such standards be periodically compared with each other, and also that their values be re-determined at intervals, in terms of a freshly set up column of mercury." With regard to the units of current and electromotive force, it was agreed that the number ·001118 should be adopted as the number of grammes of silver deposited per second from a neutral solution of nitrate of silver by a current of one ampère, and the value 1·434 as the electromotive force in volts of a Clark cell.

ELECTRICITY IN SWEDEN.—The number of electric installations in Sweden of one kind and another is constantly increasing, and a good many firms have made this branch a specialty. Of quite recent and interesting installations may be mentioned one at Östrand sawmills, where two of Laval's new steam turbine duplex dynamos, of respectively 100 and 50 horse-power, have been fixed, and where they work various machines. They are the first of this type which have been delivered, and they appear to answer very well. The dynamos are directly coupled with the turbines, and owing to the efficiency of the regulator the current is absolutely constant. The larger turbine is fitted with condensing appliances, and the smaller can be used both with and without condensing. Both turbines have governors. The current emanating from these generators is divided amongst thirty electric motors, each of 4 horse-power. At the Önan's Company at the Trallhätta Canal an electric crane has just been installed. The crane in question had previously been worked by hand power, four strong men being required. An electric motor has been placed at the crane, and the electric current is supplied by the lighting machine already at hand; the motor is easily tended by one man, so three men's wages are saved. The electric motor has been fitted with a special appliance, whereby one single handle is enough for completely working the motor.—*Engineering.*

CANTOR LECTURES.

RECENT CONTRIBUTIONS TO THE CHEMISTRY AND BACTERIOLOGY OF THE FERMENTATION INDUSTRIES.

By Percy F. Frankland,

Ph.D., B.Sc.(Lond.), F.R.S., Professor of Chemistry in St. Andrew's University, Dundee.

Lecture II.—Delivered May 9th, 1892.

Culture-media.

As already pointed out, the most varied materials have been employed for the cultivation of micro-organisms, but whilst the earlier investigators made exclusive use of liquid media, within recent years solid media have come more and more into vogue. In fact it may be said, without exaggeration, that the great advances which have been made in our knowledge of micro-organisms, during the past ten years, have been mainly due to the introduction of such solid culture-media.

It is not that the micro-organisms prefer the solid media to grow in, for as a general rule, on the contrary, they show a preference for the liquid ones. The advantage of the solid media, however, lies in the greater facilities which they afford for obtaining pure cultivations of micro-organisms, and pure cultivations are the key to bacteriological progress, just like pure reagents are indispensable to progress in chemical science.

We will turn our attention for a few minutes to this important question of preparing pure cultivations, which confronts us in every investigation connected with micro-organisms.

Pure Cultures with Liquid Media.—(1.) The simplest although but rarely available method consists in starting a growth of organisms in a liquid medium, which experience has shown is specially suitable for the particular organism which we desire to obtain in pure culture. When microscopic examination shows that this organism has abundantly multiplied in the medium, we transfer a minute quantity to a fresh portion of the same medium, allow the multiplication to take place there, and then again transfer to a fresh portion of the medium. By repeating this transference a number of times, it is sometimes possible to so purify the growth that finally only one kind of micro-organism is present.

This principle is really abundantly taken advantage of in a modified form in the fermentation industries.

Thus, in the alcoholic fermentation, the wort is artificially maintained at those temperatures at which it is a good culture medium for yeast, but a bad or indifferent medium for such organisms as those of the lactic and acetic fermentations; whilst sometimes additions are made to the wort which are inimical to these objectionable ferments, but affect the growth of the yeast only slightly or not at all. This is notably the case with sulphurous acid, which has long been used in many breweries for the purpose of excluding foreign fermentations. Again, the practice of keeping alcoholic liquids of low strength, such as beer and light

wines, fully charged with carbonic acid gas, is another case in point, as in this way the acetic organism is kept in check, and a free field maintained for the yeast. On the other hand, in the vinegar or acetic fermentation, by maintaining a strongly acid reaction, with abundant aëration, the medium is practically preserved for the undisputed development of the acetic organism.

In this way, however, absolutely pure cultures are but rarely obtained, and, in scientific investigations, the method generally only serves as a convenient means of preliminary purification, before employing some of the more exact processes to which I shall presently refer.

In connection with the use of sulphurous acid as a preservative, we may take notice of some recent experiments which have been made by Linossier, with a view to rendering our knowledge of its antiseptic action more precise.

SULPHUROUS ACID.—TOXIC DOSES PER 1,000 C.C.

	¼ hour. c.c.	6 hrs. c.c.	24 hrs. c.c.	5 days. c.c.
Brewers' yeast	200	100	20	—
Yeast (from raisins)	100	20	20	10
„ (with 0·25 grm. sulphuric acid)	(40)	(4)	(4)	—
Mycoderma vini	200	100	100	40
Aspergillus niger	50	20	10	—

The greatly increased activity of the sulphurous acid, in the presence of the merest traces of free mineral acid, is not only interesting, but might very possibly be of technical value in some cases.

In this connection I may refer to some very interesting results which have recently been obtained by Effront, in the use of mineral acids for the suppression of undesirable fermentations in breweries and distilleries.

Effront found that 100 c.c. of wort were protected from the lactic and butyric fermentations absolutely by ·025 grm. hydrofluoric acid, ·200 grm. hydrochloric acid, ·300 grm. sulphuric acid. And these fermentations were very materially retarded by hydrofluoric acid, 0·002 grm.; hydrochloric acid and sulphuric acid 0·020 grm.

If both ferments are simultaneously present, very much smaller doses of hydrofluoric acid are efficient in suppressing them : thus, 0·0008 grm. hydrofluoric acid greatly retards, and almost entirely suppresses, the more dangerous butyric ferments.

Effront further found that such additions of hydrofluoric acid, instead of injuring the diastatic power of malt, were favourable to it. In some cases the use of ammonium and potassium fluorides was preferable to that of the free acid. The pretensions of the method may be gathered from the following experiment:—

Three kilos. maize were made to yield 10 litres of mash. Using 14 per cent. of malt, there were obtained, without ammonium fluoriode, 57·02 alcohol to 100 parts starch; using 7·5 per cent. of malt, there were obtained, without ammonium fluoride, 54·30 alcohol to 100 parts starch; using 14 per cent. of malt, there were obtained, with 0·02 grm. ammonium fluoride,* 66·98 alcohol to 100 parts starch; using 7·5 per cent. of malt, there were obtained, with 0·02 grm. ammonium fluoride, 66·07 alcohol to 100 parts starch. The method has been tested on a practical scale in several German distilleries—in some cases apparently with much success—and it would undoubtedly appear to deserve trial.

2. The only reliable method of obtaining pure cultures by means of liquid media is far more complex and troublesome than that which I have described. It is known as the "dilution method," and consists in largely diluting the liquid containing the micro-organisms, and then dividing this diluted material into such a number of small fractions that each of these fractions contains not more than one micro-organism. Such a fraction then forms the starting-point for a pure culture of the particular organism.

Although the principle of this second method is obvious enough, and is comprised in these few words, yet its actual execution is in the highest degree laborious and wearisome, success often only being achieved after many abortive attempts.

An idea of the manner in which this method is carried out may be gathered from the following hypothetical case:—Suppose that it has been estimated, by microscopic examination, that about 10,000 microbes are present in one cubic centimetre: then dilute 1 to 100 c.c. with sterile liquid, and inoculate 10 tubes each with 1 c.c., each tube will contain about 100 microbes; inoculate 10 tubes each with ·5 c.c., each tube will contain about 50 microbes; inoculate 10 tubes each with ·1 c.c., each tube will contain about 10 microbes. Then dilute 1 c.c. to 1,000 c.c. with sterile liquid, and inoculate 10 tubes each with 1 c.c., each tube will

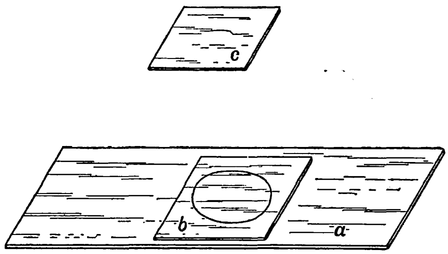
* This was added to half of the 10 litres of the mash obtained.

contain about 10 microbes; inoculate 10 tubes each with ·5 c.c., each tube will contain about 5 microbes; inoculate 10 tubes each with ·1 c.c., each tube will contain about 1 microbe; inoculate 10 tubes each with ·05 c.c., each tube will contain about ·5 microbes.

Of the last ten tubes, then, about five only would develop growths, and these would, in all probability, be derived from a single microbe each, and thus be pure cultures.

In the case of large micro-organisms, like yeast, the method is not nearly so troublesome as in the case of bacteria, for it is comparatively easy to estimate with a fair degree of accuracy how many yeast-cells are present in a given volume of liquid with the aid of the hæmatimeter.

FIG. 7.



HÆMATIMETER. (After Jörgensen.)

(*a*) Glass slide on which the perforated glass square (*b*) is cemented so as to form an extremely shallow circular cell, the depth of which is accurately determined. On the glass bottom of this cell some very small squares of known dimensions are etched. A small drop of the liquid in which the number of yeast cells is to be determined is placed in the cell, and the cover glass (*c*) placed on the top so as to be in contact with the liquid in the cell. The volume of liquid resting on each of the little squares is thus easily calculated, and by counting the yeast cells visible with the microscope in each square, the number in the particular volume of liquid is determined.

It was in this manner that Hansen, in his classical researches, first obtained cultures of pure yeast (1882). I have more recently employed the method for the isolation of the nitrifying organism, but to this I shall refer again later on.

Solid Culture Media.—Considering, then, what enormous difficulties attach to the preparation of pure cultures by means of liquid media, it may be imagined how welcome was the introduction, by Koch, of the new methods of culture on solid media, which greatly facilitated the process of purification.

The commonest solid media employed are gelatin-peptone, agar-agar, and potatoes.

I may take this opportunity of stating the precise composition of some of the more important of these solid media:—

	Gelatin-Peptone.		Agar-Agar-Peptone.
Lean beef	1 lb.	....	1 lb.
Gelatin (leaf) ..	100 grms.	Agar-agar	15 grms.
Peptone (dry) ..	10 grms.	....	10 grms.
Common salt....	5 grms.	....	5 grms.
	1,000 c.c. water.		1,000 c.c. water.

The gelatin-peptone is suitable for cultures not requiring more than 22° C. for their incubation; when higher temperatures have to be employed, the agar-agar-peptone must be used, or some other medium which will remain solid at the temperature in question, *e.g.*, potatoes, hard boiled white of egg, or coagulated blood serum. The latter was formerly the only medium on which the tubercle bacillus could be cultivated, until it was shown by Nocard and Roux that agar-agar, to which about 5-8 per cent. of glycerin had been added, formed an excellent nutritive material for these bacilli, and in fact now the addition of glycerin is almost invariably made for the agar-agar-peptone medium.

Pure cultures may frequently be obtained by simply streaking with a needle bearing the organisms under investigation over the surface of one or other of these solid materials. In so doing each organism is obviously fixed by the solid at the point where it is deposited, and the progeny to which it gives rise by multiplication grows up around it, and these growths, being more or less isolated, are pure, and further pure growths can be obtained by inoculation from them.

[Demonstration of streak growths of various organisms.]

Such solid surfaces of nutrient materials have also been largely employed by myself and others for investigating the micro-organisms of the air, for if such surfaces are exposed to the air, the micro-organisms present in the latter fall upon them in different places, and thus give rise to isolated growths from which pure cultivations can be propagated.

[Demonstration of gelatin-plates and slices of potato that had been exposed to air, and on which colonies of aërial micro-organisms had appeared.]

Plate-cultures.—A most important modification and advance upon the process I have just described, and which we also owe to Koch, consists in mixing the organisms with a liquefied jelly, thoroughly distributing them in the fluid mass, and then pouring this mixture out on a cold glass plate,

FIG. 8.

on which it rapidly solidifies; on keeping this sheltered from dust in a moist chamber at a suitable temperature, the organisms multiply and give rise to isolated colonies, as they are generally called, each of which is a pure culture.

[Demonstration of a plate-culture with its colonies.]

It is quite impossible to overestimate the benefit which this elegant process has conferred on bacteriological science. Not only does it enable us in many cases to obtain pure cultivations with great facility, but from the appearance of these colonies, when viewed either with the naked eye, or more generally with a low power of the microscope, we are often able to recognise the particular organisms with which we have to deal.

The identification of micro-organisms is often a matter of much difficulty, and entails long practice, but from the foregoing figures you will be able to form an idea of the great assistance which is frequently to be derived from a study of the colonies.

Modifications in Gelatin-plate Process.—Although 10 years have elapsed since Koch first introduced this process of gelatin-plate culture, only trifling modifications—they can hardly be called improvements—have been made in it; indeed, the process is, in many respects, so perfect and simple that it hardly admits of any. The only material modification which occasionally presents special advantages is that introduced by Esmarch, and which consists in producing the gelatin film on the inside of a test-tube instead of on the surface of a plate (Fig. 10, p. 925).

This modification becomes particularly serviceable in the study of the ordinary fermentation organisms, and what are known as anaërobic forms; for the culture can easily be incubated, in the absence of air, or in an atmosphere of any gas that it may be wished to experiment with (Fig. 11, p. 925).

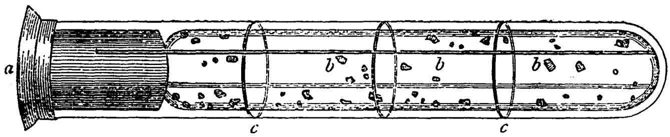
This may often serve as a particularly convenient means of identifying fermenting organisms in the presence of others, as the fermenting organisms are always capable of growing in the absence of air, and they betray their presence in the gelatin film, not only by the formation of a visible colony but by the generation of a bubble of gas, if the gelatin is made with an addition of 1 to 2 per cent. of dextrose.

Instead of using hydrogen to displace air from a culture material, to be used for the

growth of an anaërobic organism, the removal of the oxygen may be effected by means of bacterial life itself, as devised by Roux, Salomonsen, and Buchner. For this purpose a small culture tube is fitted in the ordinary way, sterilised and inoculated with the anaërobic organism under examination; it is then placed in a larger tube containing broth which has been infected with *bacillus subtilis*, or some other organism which rapidly consumes oxygen. This outer tube is then tightly closed with an india-rubber stopper, which may be further coated and sealed with paraffin. The oxygen is rapidly removed from the entire closed space by the vegetation of the *bacillus subtilis* in the outer vessel, thus permitting the growth and development of the anaërobic organism in the inner tube.

Instead of using the culture of *bacillus subtilis* in the outer tube, it is more convenient

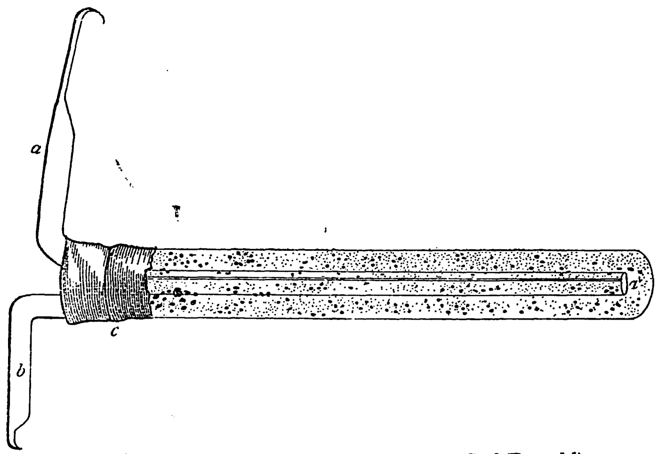
FIG. 10.



ESMARCH TUBE CULTURE WITH COLONIES.

(*a*) India-rubber cap covering cotton-wool stopper; (*b*) numerous colonies in the gelatin-film; (*c*) ink-marks on the outside of the test-tube, to facilitate the counting of the colonies.

FIG. 11.



ANAËROBIC ESMARCH TUBE-CULTURE (Carl Fraenkl).

(*aa*) Glass tube, through which hydrogen or other gas is passed into melted gelatin. (*b*) Exit tube for stream of gas. Both of these tubes are sealed in the blow-pipe, after the gas has been passing for about 15 minutes; the melted gelatin is then made to congeal on the inner surface of the test-tube, by rotating the latter horizontally in cold water. (*c*) Doubly perforated india-rubber stopper, coated outside with paraffin wax. Numerous colonies have appeared in the gelatin-film.

to employ a mixture of caustic potash and pyrogallic acid, which, as is well known, rapidly absorbs oxygen. The arrangement is shown in Fig. 12, p. 926.

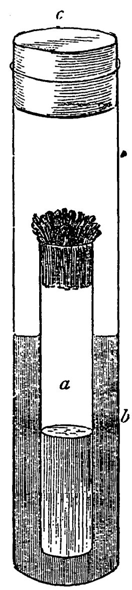
Unfortunately, a number of organisms are known which will not thrive on this gelatin medium; some not at all, and others only at temperatures above that of the melting point of the gelatin.

But, even when organisms will not grow on gelatin, the gelatin plates may sometimes still be successfully used for obtaining pure cultures. Thus, supposing we have an organism which will not grow on gelatin mixed with other organisms which do thrive on this medium, we may make use of the following artifice for securing the organism which does not grow on the gelatin.

Plates are poured off the mixture, and, in due course, the organisms which thrive on

the gelatin give rise to colonies. Now, the organisms which do not grow on the gelatin must obviously lie in the interspaces between these colonies, and, by cutting out some of the interspaces with sterilised instruments, we shall obtain these organisms purified from all those which thrive on the gelatin. This artifice has, indeed, been occasionally most successfully employed. To this we shall have to refer again, in connection with the important organisms which bring about nitrification in the soil.

FIG. 12.



ANAËROBIC CULTURE.

(*a*) Ordinary culture-tube plugged with cotton-wool; (*b*) larger test-tube containing mixture of pyrogalic acid and caustic potash; (*c*) india-rubber stopper coated with paraffin.

A special jelly has recently been devised to meet the requirements of some refractory organisms—like those of nitrification—which refuse to grow on gelatin, and which demand a medium free from organic matter. These may be most successfully cultivated on silica jelly, a preparation which is wholly destitute of organic matter, and in which the gelatinous consistency is secured by means of dialysed silicic acid. To the sterile solution of dialysed silicic acid, placed in a sterile glass dish with flat bottom, a sterile solution of the following composition is added:—

Ammonium sulphate	·4	grm.
Magnesium sulphate	·05	,,
Potassium phosphate	·1	,,
Calcium chloride	trace.	
Distilled water	100	grm.
Sodium carbonate..........	·6—·9	,,

The two are thoroughly mixed, after which gelatinisation takes place in from 5 to 15 minutes. The carbonate of soda may often be advantageously replaced by magnesium carbonate, but the medium is then not transparent.

But even when an organism grows on gelatin it is not always possible to isolate it by the ordinary process of plate-culture, for it may be mixed with other organisms which have the property of peptonising or liquefying the gelatin to such an extent that the organism in question may be crowded out, and the whole plate may have become liquid before it has had time to give rise to a colony of recognisable dimensions. This is a point which must be constantly kept in view by all engaged in isolating particular micro-organisms, and frequently necessitates the use of special methods adapted to the special habits and characters of the organisms under investigation. I may take two examples to illustrate how such difficulties have been overcome in specific cases.

The first case is that of the method which has been devised for identifying the presence of the typhoid bacilli in potable water. These bacilli in such waters are invariably associated with a large number of other forms which grow freely on gelatin and often cause its liquefaction, and as the colonies of the typhoid bacillus grow comparatively slowly, and are but little characteristic, it is quite hopeless to endeavour to detect them in an ordinary plate-cultivation of a sample of water. Under these circumstances, advantage has been taken of the ascertained fact that this typhoid bacillus is particularly insusceptible to doses of carbolic acid.

In order to apply this peculiarity to the detection of the typhoid bacilli, a number of tubes, each containing 10 c.c. of neutral bouillon, are prepared, and to these are then added from ·1, ·2, and ·3 c.c. of the following solution:—

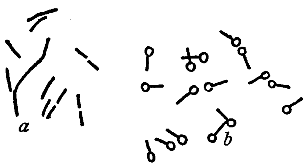
Carbolic acid	5	grms.
Hydrochloric acid	4	,,
Distilled water............	100	,,

These tubes are then inoculated with 1 to 10 drops of the water under examination, after which they are placed for twenty-four hours in the incubator at 37° C. Under these circumstances most of the microbes present in natural

waters are destroyed, whilst the typhoid bacilli multiply abundantly. From these broth-tubes, after incubation, gelatin plates are now poured in the ordinary way, the colonies of the typhoid bacilli, should they be present, can easily be discovered, and their identity proved by confirmatory tests, such as their characteristic growth on potatoes, presence of flagella, &c.

The second case, which illustrates in the most instructive manner how the special properties of a microbe may be taken advantage of for its isolation, is that which was resorted to with such signal success by Kitasato for the bacillus of tetanus. This organism, as present in the pus of a wound which has caused tetanus, is always surrounded by a number of other forms. The first step in the purification of the bacillus consists in taking advantage of the fact that it is anaërobic, *i.e.*, that it grows in the absence of oxygen, to this end the pus is cultivated in an atmosphere of hydrogen; under these circumstances it grows freely, but so do also some of the other organisms with which it is mixed. Kitasato, however, observed that there was an important difference between the tetanus bacillus and these other organisms, for he found that the tetanus bacillus developed spores at a much earlier period than any of the microbes with which it was associated. Now the possibility of arriving at a successful issue was at once apparent. Taking advantage of the well-known fact that spores are capable of resisting for some time high temperatures which are rapidly fatal to the vegetative or fully developed microbes, he proceeded to heat the cultures as soon as these tetanus spores had made their appearance, and by maintaining the temperature at 80° C. for some time, all the organisms, excepting the spores alone, were destroyed, and inasmuch as only the tetanus bacilli had formed spores, a pure culture was thus obtained.

FIG. 13.



TETANUS BACILLI. (Kitasato.)

(*a*) Sporeless bacilli; (*b*) bacilli, each bearing a spore at its extremity, giving rise to club-shaped forms.

I have not hesitated to bring before you these illustrations, although at first sight they may appear foreign to the subject of my lectures, because I am convinced that it is of the utmost importance that those who are engaged in one department of bacteriology, *e.g.*, in that which deals with fermentation phenomena, should constantly bear in mind the methods which have been found useful, and the discoveries which have been made in other departments of the same science.

In conclusion, I would draw your attention to Figs. 14, 15, and 16, representing some of the best known pathogenic forms of micro-organisms.

Miscellaneous.

IRRIGATION IN INDIA.

According to any official summary, issued from Simla, of the review of the Government of India of the revenue and expenditure connected with irrigation, the record of the past year shows how very remunerative such works are. On productive works, to the end of 1890-91, the direct outlay has amonnted to Rx. 25,465,000, upon which a net return of 4·81 per cent. is derived, without taking into account the old irrigation system in Madras. If this were included, the average return from all productive works would amount to 5·8 per cent. These aggregate results include figures relating to projects such as the Chenab Canal, in the Punjab, and the Sangham and the Periyar projects in Madras, which were still in various stages of construction during the year

under review. The capital outlay on these is unproductive until complete, and the general average return is reduced in a corresponding ratio. The same remark applies to the large addition made to the capital outlay of the Lower Ganges Canal, on account of the new aqueduct over Kalinadi, at Nadrai, as it will take time before irrigation can recover from the check caused by the failure of the original aqueduct. The figures also include those relating to the Orissa project, in Bengal, and the Karnul Canal, in Madras. These two works were first undertaken by companies under a 5 per cent. guarantee from Government, but being entirely unproductive the companies were bought out. The capital outlay on these two projects has amounted to Rx. 4,585,919, on which large outlay there is less than no return, the working expenses during the year having exceeded the receipts by Rx. 12,707. On the other hand, the returns from some of the works are extraordinarily good. Out of 35 irrigation works classed as productive, 15 yielded over 4 per cent. on their capital outlay, ranging from 40·2 per cent. in the case of the Cauvery system in Madras to 4·5 per cent. in the case of the Agra Canal in the North-West Provinces. On the whole, returns from the systems which really fulfil the condition of being productive are more than sufficient to cover the deficits on the systems which, though classed as productive, do not attain to the necessary standard. The aggregate profit to the State to the end of 1890-91 on account of the former, after paying 4 per cent. interest on capital outlay, amounts to Rx. 10,735,022, whereas the deficit on account of the latter, including accumulated arrears at simple interest, amounts to Rx. 6,620,520. The net profit, therefore, amounts to Rx. 4,114,502. In 1886 the area irrigated is shown as 5,292,733 acres, bringing in a gross revenue of Rx. 1,813,185. In 1890-91 the area was 7,172,468, and the return Rx. 2,312,787. The estimated value of crops grown under major and minor works in 1890-91, excluding those in Sind, for which figures are not available, was Rx. 24,544,110 from an area of 7,984,275 acres, giving a value of about Rx. 3 per acre. The estimated value of the produce of one year is thus nearly equal to the whole of the direct capital outlay incurred on works sanctioned. The projects are Jhelum, Kalingaroyen, Chenab Extensions, and the Lower Ganges Canal, which it is reckoned will irrigate 1,291,260 acres, and return a net revenue of 13·30 per cent. The Chenab Canal Extension project has just been sanctioned, and will take precedence of the Jhelum Canal, sanctioned in 1888, funds for both being available. The Kalingaroyen Canal in Madras has also been sanctioned, but the commencement of work has been deferred for the same reason. The Lower Ganges Canal Extension project has been submitted to the Government of India by the North-West Provinces Government, but has been returned for revision. In addition to the above, a large and profitable outlay is contemplated on works in Upper Burmah, where scientific irrigation is still in its infancy. The Government of India is also awaiting the receipt of proposals from the Bombay Government for the improvement and extension of irrigation in Sind, upon which a committee assembled in the early part of the current year.—*The Times.*

HORSE BREEDING IN BELGIUM.

According to a recent report by the United States Consul at Brussels, Belgium possesses two pure equine races, the Ardennes horse, native of the valley of the Meuse, and the Frisian, a species of which inhabited the sea-coast. From the union of these two breeds issued the Brabançon horse. The draught horse in Belgium is generally divided into three grand divisions—(1) the race of the littoral, (2) the Ardennes, and (3) the Brabançon. Great care has been taken in the breeding of horses in Belgium, and the animals bred there are, with the exception of the shire horses of England, the largest draught horses in the world, and finely proportioned. The Ardennes horse, which is perfectly adapted to mountainous regions, is an excellent type of the light draught horse. This animal is, however, rapidly disappearing, owing to the fact that the Luxemburg farmers prefer the heavy draught horse, and the introduction of large heavy stallions into the province from Brabant and Hainault has almost completely transformed the breed. The export to Germany and Austria of the best stallions has also contributed greatly to the disappearance of the stock. Ardennaise colts readily sell before they are a year old, the price varying according to their condition. For several years much attention has been devoted to the improvement of the Brabançon horse. The line of the back is now much straighter, the neck and shoulders more proportionate, and the legs large and clean. This animal harnessed to one of the heavy carts of the country, weighing about 3,000 pounds, pulls on the level a load weighing from 6,000 to 10,000 pounds, and works from eight to ten hours daily. The results of the exhibition of Paris in 1878, Brussels in 1880, and Antwerp in 1885, prove that there are now no distinctly pure breeds in Belgium, although such have existed. At the present time there remain but two varieties, the heavy and light draught horse. The special characteristics of the Belgian draught horse are stature, form, strength, and breed. He has less bulk and strength than the Clydesdale or shire horse, but is better bred and has more energy. He has more bulk and strength than either the Percheron or Boulonnais horse, and possesses as much energy. About the year 1850, the Belgian Government established, at Tervueren, a depôt for stallions. This was not a stud, but simply an establishment where stallions were admitted, the number being limited to sixty-five. Thoroughbreds, half-breds, and a few Percherons were admitted, but no

native stallions were accepted. When the Government stud existed, it bought annually a certain number of stallions, which were collected in a central depôt until the end of February, when they were distributed, for gratuitous covering, throughout the provinces until July. The cost per stallion per annum to the Government was about 2,000 francs. The number of coverings averaged about 36 per stallion, which resulted in from 900 to 1,000 colts. After the Government stud was suppressed, horse breeding was abandoned to private enterprise, encouraged by subsidies. Since 1841, there have existed in the Belgian provinces regulations, approved by the Government, for the improvement of the equine race. These regulations were framed, in the first place, to prevent breeding from stallions judged unfit to improve the race, as far as being destined to cover mares other than those of the owner; and, secondly, to institute a system of prizes and competition and of registration, to the profit o owners of stallions and mares. Obligatory examination is in force in all the provinces. Only stallions approved by a Commission may be publicly employed. The encouragements offered are as follows: —Local competition prizes for colts and stallions three years old, and from four to nine years; provincial prizes for the best, or the two best, stallions, irrespective of locality, and a registration prize accorded to stallions, which at five years of age have obtained a first prize in the category of stallions from four to nine years. In the provinces of Antwerp and Liège, the examining commission is limited to the examination of the value of the stallions submitted to their examination, and declarations as to fitness for breeding purposes. In the province of Antwerp, there are two prizes for each of the three meetings, the first 500 francs, and the second 340 francs. In the province of Liège there are four prizes, divided between four meetings of heavy draught stallions from three to seven years of age. According to the last agricultural census, the number of horses in Belgium amounted to 271,975; about 50 horses to every 1,000 inhabitants. The average selling prices during the years 1890 and 1891 were—stallions, 3,000 to 4,500 francs; mares, 1,800 to 2,400 francs; and colts, 2,000 to 2,500 francs.

AGRICULTURE IN BERMUDA.

The principal productions of Bermuda are onions and potatoes, which are chiefly exported to New York and Boston during the months of March, April, and May, commonly called the "crop season." The United States Consul at Bermuda says that potatoes are usually planted in December and January, except in exposed places, where they are not planted until February, so that they may escape the high winds of winter. The seed potatoes are imported from New York, Nova Scotia, and Prince Edward Island in the winter. These potatoes are cut in sections, one or two eyes in each section. The ground being well manured, the potatoes are planted in drills about 20 inches apart. When half-grown, artificial manure and castor pumice are thrown around the plants. In about 90 to a 100 days after planting, the potatoes are fit to dig. They are sorted in first or second sizes, in accordance with the Colonial Inspection Act, and packed in barrels. About eight barrels of first size potatoes from one barrel planted is considered a fair yield, although twelve and even fifteen barrels is not uncommon. Onions are grown from the red and white onion seed imported from the Western Islands and the Azores, by way of London and New York. This seed is packed in hermetically sealed tin cases, and is transferred by the importer to common black pint and quart bottles, which are sold at 75 cents a pint. The seed is planted in beds from 50 to 100 feet long and about 4 feet wide, with walks between the beds for convenience in cleaning and weeding the young plants, which, when sufficiently grown, are set out in permanent beds, where they increase in growth and the bulbs begin to fill. Onion seed is sown in September and October, and the plants are set out in December and January. The harvesting of the onions begins in the latter part of March and ends the latter part of May. Onions are put up in boxes holding about fifty pounds. Farmers bring their potatoes and onions to the town of Hamilton for sale or shipment. Many other vegetables are grown in Bermuda, but with the exception of beets, not in sufficient quantities for exportation. Very little fruit is grown. There being no frost, flowers bloom all the year round, and lily buds and bulbs are largely exported to the United States. An attempt at silk culture is, says Consul Sullivan, being made by an enterprising Bermudian, who has strong hopes for the success of his experiment. In many cases the farms are owned by the farmers—none are owned by companies. Merchants and others who own land rent it out at so much a year, or on shares. Bermuda was originally laid out in parishes, of which there are nine. These were subdivided into shares of land, in 1690, each share containing 25 acres. This still remains so, and some tenants rent several tracts of land in different localities. Not more than 50 acres are usually held by one person. Portuguese from the Western Islands are large growers of produce. They are generally industrious and thrifty. Under what is known as the Alien Act, no person who was not born on British soil and is not a British subject can purchase and hold land in Bermuda. Permanent investment in land by a foreigner is not allowed.

THE FISHERIES OF CANADA.

The sea fisheries of Canada, which are situated off the coasts of Nova Scotia, New Brunswick, Prince Edward Island, Quebec, and British Columbia, are among the richest and most important in the world,

while according to a report recently issued by the Canadian Government, the fresh-water fisheries of the great lakes and rivers of the country are nowhere to be surpassed. During the last few years there has been a steady increase in the value of the product of fisheries, the increase in 1891 over 1890 amounting to 1,263,176 dollars and over 1888 to 1,559,568 dollars. There was an increase in the value of the yield in each province except British Columbia and Ontario, the largest increase having been in New Brunswick. The number of boats employed in the fisheries of the several provinces in 1891 was 31,464, and the value amounted to over 3,000,000 dollars. The number of men engaged was 65,575, and the total value of all the fishing material was over 7,000,000 dollars. British Columbia employs about 700 men and 30 vessels in the seal fishery. A Fishery Intelligence Bureau was inaugurated on a small scale in 1889, which appears to be much appreciated by those interested in the fishing industry. In 1890, there were eleven Government fish hatcheries in operation, and the number of eggs collected in the autumn of that year for subsequent hatching was nearly 145,000,000. Another fish hatehery has recently been established at Ottawa. The great benefit of these hatcheries to the fisheries generally is nniversally acknowledged, and it is said that the heavy runs of salmon in recent years on the Fraser River are largely due to the operations of the hatchery there. The yield of the Canadian fisheries in 1891 was 18,978,078 dollars, or more than four times as much as it was in 1890. In addition to the above, large quantities of fish are annually consumed by the Indians, particularly in the North - West and British Columbia, of which no account can be obtained. For the period comprised between the years 1879-81, the value of fish so consumed has been estimated at about 50,000,000 dollars. As regards the yield by provinces for the period comprised between 1869 and 1891, Nova Scotia has produced during this period 47 per cent., or nearly one-half of the total yield, New Brunswick, 19 per cent., and Quebec 14 per cent., the three provinces having yielded 80 per cent. of the total. The fishing industry in British Columbia is yet quite in its infancy, but the opportunities for its development are said to be most advantageous, and the deep-sea fisheries are unsurpassed in wealth and variety. The fisheries of the great lakes are the largest and most important fresh-water fisheries in the world; and the great value of the Canadian portion of these fisheries is not generally appreciated. The area of fresh water belonging to Canada in the Lakes Superior, Huron, Erie, and Ontario is about 72,700 square miles; and, in 1890, 1,203 vessels and boats, manned by 2,920 men, using 1,441,695 fathoms of nets, were employed in fishing therein. Whitefish, salmon, and lake trout, sturgeon, herring, bass, and pickerel are the principal fish. According to the census returns of 1890, the fish caught on the United States sides of the lakes in that year showed an increase of 58 per cent. in value, as compared with 1880; while the value of the fish caught on the Canadian sides in the same year showed an increase of more than 350 per cent. on the catch of 1880.

SMYRNA SPONGE TRADE.

The following extracts from the reports of Mr. F. Holmwood, Her Majesty's Consul-General at Smyrna, on the sponge trade of Turkey, is quoted from the *Board of Trade Journal*:—

"The value of the sponge trade during the year 1891 is stated to have diminished from 20 per cent. to 25 per cent., as compared with that of the preceding year, and this statement is borne out by the diminution in the amount of the 'charitable dues' levied by the communities of the various islands interested in the trade, viz., Symi, Calymnos, and Halki.

"The 'charitable dues' are a tax levied by the communities of the different islands interested in the sponge-fishing industry, who with the proceeds are enabled to defray the expenses incurred in the maintenance of the doctors, dispensaries, schools, &c., in their respective islands. It is leviable at the time of sale to the amount of 2½ per cent. on the value of the sponges sold, the seller paying 1½ per cent. and the buyer 1 per cent., and is considered obligatory upon all.

"The amount of sponges of the best quality was less than that obtained during the season of 1890, but very high prices were given by merchants for those of the finest quality, especially for those taken at Mandruha and Crete, where the average size of the finest sponges exceeded that of those fished during the previous season.

"Sponges of inferior quality, especially those taken at Zohara, were sold at very low rates.

"While the districts in which the sponge-fishing industry is carried on are showing signs of exhaustion, on the other hand new fields are discovered from time to time; but it is to be feared that the increase in the produce of the season afforded by the discovery of new fields does not altogether compensate for the loss occasioned by the exhaustion of districts which have long been in use.

"With regard, however, to the number of men employed in the industry, a considerable increase is recorded. It appears that, whereas some years ago, to each boat using the diving apparatus, four divers were allotted out of a crew of 15; now six, and even as many as eight, divers are employed, the crew often numbering 20 all told.

"Unfortunately, the evils mentioned in a former report, as tending to reduce, if not to destroy, this industry, still continue, and especially the dishonesty of the men employed, who not infrequently take advantage of the faulty system of prepayment of divers, which obtains in the trade, to rob their employers.

"The evils referred to were as follows:—

"First, the competition of the American sponges, which, though inferior in quality to the finer sorts of sponges obtained here, are able to compete with the coarser kinds in the European market.

"Secondly, the thoroughly faulty system that obtains with regard to the hiring of the divers and crews by the boat owners, who, being compelled to pay large sums in advance to the divers before the boat starts, are generally obliged to have recourse to capitalists, from whom they borrow money at usurious rates of interest (16 per cent., 20 per cent., and even 24 per cent.), and thus encumber themselves with heavy debts amounting to at least £1,000 for each boat before a penny has been earned. Again, when all is ready, the advance money demanded by the sailors and divers paid, and the contract duly signed, it is not an uncommon occurrence for one or more of the men to demand an extra gratuity, and to refuse to work unless their employer complies with the most preposterous demands; the boat owner is then obliged to give way, or else to abandon the enterprise, as, in the present state of the law, the only legal measure he can adopt is to bring an action against his dishonest *employé* for recovery of debt (a measure obviously useless in cases where the *employé* is already indebted to his employer, and unable to pay the debt, except by honest fulfilment of his part of the contract).

"Thirdly, the introduction of the diving apparatus, though it gave at first a great stimulus to the trade by enabling divers to obtain a greater quantity of sponges, has had an unfavourable effect by exhausting the supply of sponges in the shallower waters, and thus necessitating recourse to the deeper waters, where the risks of this dangerous occupation are increased. The divers are now obliged to descend from 25 fathoms to 32 fathoms, whereas the instructions accompanying the diving apparatus give 20 fathoms as the maximum limit of depth for which they can be used with safety.

"Fourthly, the appearance of a submarine plant of rapid growth, which covers the sponges, and causes them to rot, seemed likely to prove the most serious evil with which the trade has to contend, had it not been diminished in extent. Recently, some specimens of this plant have been sent to be examined by scientific authorities in Europe, and it is hoped that a means will be suggested by which the evil may be wholly removed.

"Again, as more divers are employed in each boat, larger sums are now required to fit out the boats; and it must also be added, that the risks of the occupation have increased, as divers descend to greater depths to obtain the sponges. As many as 80 cases of fatal accidents are reported as having occurred among divers using the apparatus during the past season.

"The boats in which the diving apparatus is used number 126, with crews amounting in all to 2,520 men. Boats, in which the naked divers are employed, number 140, with crews amounting to 980; while 720 men were employed in 180 boats in which the trawling apparatus is used.

"The practice of fishing in the winter season is becoming more general, but, as the districts in which the winter fishery is carried on are gulfs or places near the coast, and thus quite distinct from those used during the summer, the results of the summer fishery are not thereby affected.

"Fortunately, the reports of the parasitical weed, whose appearance in the sponge districts some years ago caused so much anxiety, show that the evil continues to decrease.—*Nos.* 764, 894, *and* 1,062, *Foreign Office Annual Series.*

AUSTRIAN CO-OPERATIVE SOCIETIES.

Her Majesty's Secretary of Embassy at Vienna says, that the signal success of the co-operative movement in Germany has led to the establishment in Austria of numerous institutions having for their object the improvement of the economic condition of the working and trading classes by means of combination. As early as 1868 there existed in the great industrial centres of Northern Bohemia, Moravia, and Lower Austria, 330 institutions of this kind, with a capital of 4,500,000 florins (about £375,000); this number in 1889 had increased to 1,916. Of the former total about 25 per cent. were associations for the supply to their members at cost price of food, firing, and other necessaries, while 70 per cent. were devoted to the loan and banking departments; and, as in 1889, the proportion of the latter had amounted to 1,464, they seem destined to hold their own against the productive and distributive sides of co-operative organisation. The Austrian Government, with a view to bringing into play the forces of individual exertion and economical thrift, and in order to counteract socialistic theories and inclinations among the trading and working classes, passed an Act dealing with the *Erwerbs und Wirtschaftsgenossenschaften* (business and industrial co-operative societies). In this Act, the scope of the *Genossenschaft,* as originally concerned, is considerably extended. The object is declared to be "the furtherance of the industrial gain and economy of the associates, by means of carrying on business in common," thus permitting not only production, distribution, and loan associations, but also the conduct of affairs which come under the commercial code and constitute ordinary business operations, such as buying and selling land, agricultural and forest products, with all the varieties of ordinary undertakings within the sphere of industry. Among the societies started according to the enactments of this Act, distributive societies show the greatest amount of variety. These may be divided into four classes. (1) Those established in certain localities, towns, and districts, and which, if working in the general supply business, keep extensive stores and warehouses in public thoroughfares,

They derive their custom from all classes of the population, every purchase being paid in ready money, and the profits divided at the end of the year. Membership in some of these *Consumvereins* reaches the figure of 20,000. They often compete severely with shop-keepers and small traders, and as they frequently extend their dealings beyond their own members, in contravention of the law which secures exemption from certain taxes, they have repeatedly been made the object of fierce antagonism on the part of those who think themselves injured by them. (2) Societies in connection with the great bodies of workmen in industrial undertakings, and in State and private railways. These are worked on the principle of business management and profit sharing, and give facilities to their members by granting them credits within a certain per centage of their wages. (3) Societies for supplying raw material to tailors, shoemakers, basket-workers, &c. These have been established to enable small tradesmen to compete with manufacturers on a large scale, and with a view to resisting the sweating system. In some cases, such as mother-of-pearl workers, and button makers, a special reason for combination lies in the want of adequate capital to buy the high-priced materials at reasonable rates. In the tailoring, bookbinding, and other small trades, combination has proved ineffectual in resisting the combined advantage of machinery and capital. (4) Under this heading come different kinds of stores which mostly, with the assistance of employers who supply both buildings and capital, form part of the benefit institutions of factories. Though not universally favoured by the working-classes, who feel the necessity of purchasing from them as an interference with their freedom of choice, many are in a prosperous condition, and some, such as the co-operative store in connection with the arms factory at Steyr, with a membership of 4,000, are carried on upon a scale of magnificence. The inspectors suggest that it would add considerably to their popularity were the workmen always to have a share in the management. Other forms of distributive co-operation need only passing mention. Among these are the benefit building societies, established for the purpose of buying sites in outlying districts of large towns for lodging houses, &c. These institutions are patronised chiefly by clerks and *employés* drawing monthly or annual pay, and only benefit the working-classes indirectly by relieving the overcrowded condition of more densely populated districts, and thus lowering rents. Passing to productive associations, it may be said that these have, as yet, shown no satisfactory development. Their total number is a little over 200, and of these more than one-half have their business in the metropolis; the trades for which they exist are piano makers, turners, bronze workers, potters, and bakers. The last and most important are the associations of credit—the most highly developed of the class, in possession of great and growing funds, and a highly effectual means of diffusing capital among those who would otherwise fall into the hands of usurers, and of enabling the small tradesmen to compete with the capitalists. One of the principal of these institutions is a general trading bank in Vienna. The objects of this institution are—(1) the provision of machinery and tools, to be paid for by instalments, as agreed between the tradesman and the society; (2) the granting of loans on account of debts due by private persons, this form of loan applying especially to cases when in order to obtain contracts, caution money has to be deposited, or part of the sum contracted for has to be left by way of security for the carrying out of the work; (3) the establishment of warehouses for industrial products, and granting advances for the goods stored in them; (4) effecting sales on commission of the goods stored in these warehouses; (5) the formation of associations where industrial undertakings can be carried on, and motive power used in common.

Notes on Books.

A Handy Book for Brewers. By H. E. Wright, M.A. London: Crosby Lockwood, and Son. 1892.

The object of this book is stated to be "to give the conclusions of modern research, in so far as they bear upon the practice of brewing, in such a form that a novice of fair intelligence may understand them." The author commences with a general introduction in which the whole process of the manufacture of beer is described, from the malting onwards. Technical details are thus taken up in succeeding chapters. The subjects treated include "Barley, malting, and malt," "Water for brewing," "Hops," "Chemistry as applied to brewing," "Ferments," &c. There are also special chapters on the various processes, and a final one on "The brewery and plant."

General Notes.

Chicago Hotels.—A small Committee has lately been appointed by the Executive Committee at Chicago to make special efforts to secure moderate rates for visitors to the Exhibition, on the occasion of the dedicatory ceremonies next month and during the Exhibition. Much work has already been done in this direction by the "Bureau of Public Comfort," and it is intended that the hotels of the city shall be classified, and a uniform scale of charges published. This can be more readily done in America, where it is the practice to make an inclusive charge for board and lodging, than over here.

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

CANTOR LECTURES.

RECENT CONTRIBUTIONS TO THE CHEMISTRY AND BACTERIOLOGY OF THE FERMENTATION INDUSTRIES.

By Percy F. Frankland,

Ph.D., B.Sc.(Lond.), F.R.S., Professor of Chemistry in St. Andrew's University, Dundee.

Lecture III.—Delivered May 16, 1892.

Having now made ourselves acquainted with the important methods of handling micro-organisms which have been developed mainly during the past ten years, we must turn to consider some of the principal results which have been achieved by their means.

It must be noticed, in the first instance, that during the greater part of these ten years, the modern methods of bacteriology have been mainly employed to elucidate problems connected with the cause and communication of disease, and in this department truly astonishing strides have been made. It is only within the latter half of the decade that much serious work has been undertaken in connection with the chemical changes brought about by micro-organisms, but there can be no doubt that this side of bacteriology will annually absorb more and more attention, as the problems involved are really of more fundamental importance, although not invested with so much sensational interest.

There can be no doubt that the investigations of a practical character, in which these recent bacteriological methods have been utilised, which have attracted most attention, are those of Christian Hansen, whose name is so familiar throughout the brewing world. I do not propose entering into a description of his researches, which have been very comprehensively dealt with here in a course of Cantor Lectures by Mr. Gordon Salamon, in the year 1888. We may, however, summarise the work of Hansen by saying that whilst Pasteur showed the advantages of brewing with yeast free from other micro-organisms, Hansen has further industrially demonstrated what Pasteur had also indicated, viz., the advantages of brewing with particular species or varieties of yeast. As far as this country is concerned, however, Hansen's researches have hitherto been of little more than theoretical interest; scientific men and brewers have made themselves acquainted with his results, and in some cases have conducted laboratory experiments on the same lines, but in hardly a single instance, as far as I am aware, have his methods been introduced or adopted on a large scale.

But although Hansen's methods have gained no footing in this country, it must not be supposed that they have undergone no further development; on the contrary, we learn that his pure yeasts have been adopted in bottom-fermentation breweries in all parts of the world, and even in top-fermentation breweries they have been used with great success in Denmark, Belgium, France, and Australia. Of great theoretical interest are some recent researches of Hansen's which open out great possibilities in the future. In these investigations he has found that it is possible to produce artificial varieties of yeast, the acquired properties being transmitted from one generation to another, apparently indefinitely; it is obvious that we have here the beginnings, on a microscopic scale, of practices which have long been carried out on the higher plants in floriculture.

The production of more or less permanent varieties of other micro-organisms than yeasts is also attracting much attention at the present time, and is throwing much light on the subject of heredity and evolution.

A striking instance of variation has recently come under my observation in connection with a bacillus which has the property of fermenting calcium citrate; this power it has continued to exercise for years, but if it is plate cultivated, and one of the colonies then introduced into a solution of calcium citrate, I find that the latter is never fermented, the bacillus having lost its fermenting power through cultivation in the gelatin medium. If, however, one of the colonies in question is put into a broth-solution of calcium citrate, the latter is fermented, and on then passing the bacillus from this to the calcium-citrate solution, which it before failed to act upon, it now sets up fermentation in this also.

Perfectly similar phenomena are also fre-

quently observed in the case of pigment-forming bacteria; the power of producing the particular pigment may be permanently lost unless some special treatment is resorted to in order to restore the power. One of the most striking instances of this kind is that of the well-known *bacillus prodigiosus*, which produces a magnificent crimson pigment, the power of producing which becomes, however, gradually lost if it is continuously cultivated on gelatin or agar, and immediately restored if the organism is transplanted to potatoes.

This possibility of producing more or less permanent varieties of micro-organisms has greatly complicated the problems of bacteriology, and shows how very far we still are from having any sound basis on which to establish distinct species. The construction of species was first attempted on a morphological basis, difference of form being made the dominant principle. It is unnecessary for me to remind you how completely this artificial morphological classification has collapsed. The classification has been attempted on physiological lines, but this has proved equally untenable, for a given organism may be made to entirely modify some of its most striking physiological characters. Thus, a fermenting organism, as I have shown, may be made to lose its fermenting power—a pathogenic form may be deprived of its sting, so to speak, and lose its virulence either temporarily or permanently. Again, the construction of species has sometimes been attempted on culture characteristics, such as the liquefaction or non-liquefaction of gelatin, production of pigments, appearance of colonies, &c. All these points, although extremely valuable for purposes of diagnosis, cannot be applied so rigidly as to warrant their being used for the purpose of absolute classification. Perhaps a point which has been more implicitly believed in than almost any other, for the purpose of distinguishing micro-organisms, is their property of producing or not producing spores under prescribed conditions. This test, however, entirely breaks down by the light of the extremely important discovery by Roux and Chamberland of what is called "sporeless anthrax." These investigators have shown that, by suitably cultivating the anthrax bacilli in media to which a small amount of an antiseptic has been added, a race of bacilli is obtained which differ from the ordinary anthrax bacilli in being unable, under any known conditions, to form spores. This asporogenic character is permanent, and is maintained even though they be cultivated on the most diverse media, aye even though they be made to pass through the system of an animal, for they are not in any way attenuated but fully virulent. We must not hesitate to confess, therefore, that although our knowledge of micro-organisms has so enormously increased within recent years, we are still destitute of any foundation on which to establish a differentiation into species. It is, moreover, precisely this instability of properties, and the comparative facility with which they can be moulded at the will of the experimenter, that renders the study of micro-organisms so fascinating and attractive.

FIG. 17.

SPORELESS ANTHRAX BACILLI.

A point of great interest in connection with the introduction of pure yeast fermentations is the influence of the pure yeasts on the formation of the well-known by-products—glycerin, succinic acid, and higher alcohols. There was a very general impression in some quarters that the higher alcohols were due to fermentations induced by extraneous yeasts, and that each particular yeast, if employed in a pure state for fermentation, would give rise to only one alcohol. This matter has as yet been but very imperfectly investigated, but, from some recent experiments of Perdrix, it appears very probable that the amyl alcohol, which is such a constant product of the fermentation of potato-mashes, may be the result of a subsidiary fermentation set up by anaërobic bacteria, which are specially favoured by the presence of starch.

There is also some evidence that the formation of higher alcohols is, to a certain extent, dependent on the temperature of fermentation. Thus, Lindet has found that there is a somewhat larger proportion of higher alcohols produced in fermentations carried on at a high than at a low temperature, thus using the same mixture of top and bottom yeasts; in each case the following results were obtained:—

Temperature of Fermentation.	Crude Alcohol.	Higher Alcohols.	
Deg. C.	c. c.	c. c.	Per cent.
32–35	675	3·9	·58
25–27	1607	9·6	·59
19–21	1834	9·9	·54
8–10	1877	9·7	·52

It is much to be regretted that these experiments were not made with pure yeasts, as the interest attaching to them would have been very much greater.

In the matter of glycerin production, it also appears, from Borgmann's experiments, that less of this material in proportion to the alcohol is formed when pure yeasts than when the ordinary mixed yeasts are used. Thus :—

	Ordinary Lager beers.		Beers produced with Carlsberg.	
	Max.	Min.	No. 1 yeast.	No. 2 yeast.
Alcohol : Glycerin...	100 : 5·497	100 : 4·140	100 : 2·63	100 : 3·24

As regards the theory of the alcoholic fermentation, it must be admitted that we are still very much in the dark, especially as Pasteur's original explanation of the fermentation phenomena being due to yeast life, in the absence of oxygen, is not borne out by recent experiments. For, not only has it been shown that the same changes take place when the yeast is grown with abundant access of oxygen, but the quantity of the fermentation products is actually greater than when oxygen is excluded. In defence of Pasteur's theory, this has generally been accounted for by assuming that the presence of oxygen increases the proliferation of the yeast, and that the larger number of yeast cells then give rise to a larger quantity of fermentation products than do the smaller number of yeast cells which are present when oxygen is excluded. Some very interesting experiments have recently been instituted by Mr. Adrian Brown, which go very far towards undermining this ingenious explanation.

In these experiments Mr. Brown has estimated the quantity of yeast, both by counting the number of cells with the haematimeter, and also by actually weighing its amount. He conducted his experiments in such a manner that the number of yeast cells could not multiply during the fermentation, thus avoiding this complicating factor; and, in all cases, he found that there was more alcohol produced, when oxygen was abundantly supplied, than when it was excluded from the yeast. Thus—

No Multiplication of Yeast Cells.

(*a.*) Air excluded....	3·35 grms. alcohol in 120 c. c.	
(*b.*) Air supplied	3·56 ,, ,, ,,	

Thinking that, in the above experiment, the fermentation of (*b*) had been promoted through the agitation occasioned by the current of air passed through the liquid, another experiment was made, in which air was bubbled through the one portion and hydrogen through the other. The following result was obtained :—

No Multiplication of Yeast Cells.

	I.	II.	III.
(*a.*) Stream of Hydrogen...	6·20	4·882	2·26 grms. dextrose decomposed.
(*b.*) ,, Air	7·38	5·289	2·45 ,, ,,

LONGEVITY OF YEASTS.

I may at this stage opportunely refer to some interesting results which have recently been obtained by M. Duclaux on the longevity of yeasts. M. Duclaux has had the unique opportunity of examining a number of the yeast cultures which were employed by Pasteur in his "Etudes sur la Bière," in the years 1873 and 1874, and he has not only determined whether these cultures still contained living yeast-cells, but also the proportion of alcohol, acid, &c., present in each, from which it is possible to draw conclusions as to the conditions which favour or militate against the preservation of yeast life. His results are summarised in the Table, p. 936.

From the Table it will be seen that age alone has had little or no effect in causing the death of the yeasts; for, of the six deaths, one actually occurred in the youngest culture, which was 11 years old, whilst the yeast in the oldest culture—17 years—was still alive. The principal cause which accelerates the death of the yeast appears to be the acidity of the medium, and, in all the dead cultures a considerable proportion of free acid was discovered, whilst in most, also, the amount of alcohol was particularly high.

The longevity of yeasts is of special importance in connection with the preservation of pure cultures of yeasts. It has been found by Hansen and Jörgensen that pure yeasts are best preserved in a 10 per cent. solution of cane sugar in distilled water. In such a solution the specific properties of the yeast remain unimpaired for years, whilst, if the yeast is preserved in wort-gelatin, its properties frequently undergo very serious alteration. I have also myself found that bacterial ferments are very liable to lose, more or completely, their fermentative power by continuous cultivation in a solid medium like gelatin; and

sometimes this power is lost even by a single plate cultivation; and this is a point which all engaged in the study of fermentation phenomena should carefully bear in mind.

Behaviour of Yeasts under the Influence of Heat.

In connection with the remarkable vitality of yeasts, I may also refer to their behaviour under the influence of heat, as this has been recently made the subject of special investigation by Kayser. This investigation is the more welcome, as the previous information relating to this point is full of discrepancies and contradictions.

Kayser's experiments were made with a number of well-known yeasts in a state of purity, their resistance to heat being determined, both in the moist and dry condition, as well as in the form of spores. The results are summarised in the following Tables; in all cases the temperature indicated was maintained for a period of five minutes:—

Action of Heat on Yeasts and their Spores.

(*a.*) *In the Moist State.*

	45° C.	50° C.	55° C.	60° C.	65° C.
Yeasts.					
Bass..........	L L	L L	L L	L L	D D
St. Emilion ..	L L	L L	L L	D D	D D
Augustinerbräu.	L L	L D	D D	D D	D D
Hofbräu	L L	L L	D D	D D	D D
Spatenbräu	L L	L L	D D	D D	D D
Neunkirchen ..	L L	L L	L L	L L	D D

Sacch. Pastor. .	L L	L L	L L	D D	D D

N.B.—L = living, D = dead; two experiments were made at each temperature.

The principal points brought out by this Table are firstly that the low-fermentation yeasts are mostly more susceptible to heat than the high-fermentation forms, and, secondly, that although the resistance of the spores is greater than that of the vegetative cells, yet the difference in this respect is far smaller than that which generally subsists between bacilli and their spores.

Sacch. Pastorianus	100—105	115

The Augustiner-yeast is so delicate that it does not stand the slightest heating in the dry state—in fact, it sometimes perishes during desiccation, even at the ordinary temperature of the air. The hardiest form in the dry state was the yeast of St. Emilion, which is a high fermentation variety obtained from wine.

In some cases, the remarkable phenomenon was observed, that the progeny of spores, which had resisted a high temperature, was endowed with the power of withstanding a temperature higher than was normal to the particular variety, thus affording evidence of the transmission of hereditary characters, which, as we have already seen, is such an important element in the case of these low forms, as well as with more highly organised forms of life.

CARBOHYDRATES FERMENTABLE BY YEASTS.

Much attention has from time to time been bestowed on ascertaining what carbohydrates are fermentable by yeasts, and great differences of opinion have frequently existed as to this point. Before it was possible to command pure cultures of yeast, the matter could not be investigated with any degree of precision, for ordinary yeast may contain numerous other organisms which, on the one hand, may transform some unfermentable carbodydrates into fermentable ones, whilst these other micro-organisms may themselves give rise to alcoholic fermentations which may be confounded with the alcoholic fermentation of yeast.. The older observers thus frequently record as fermentable by yeast substances which more recent, refined, and accurate experiments have shown to be unaffected by it when presented to them in a pure state. Until recently, it was generally recognised that the carbohydrates fermentable by yeast were—dextrose, lævulose, maltose, and cane-sugar (after inversion by the yeast itself), whilst opinion was much divided as to the fermentability of galactose. Recent experiments by Duclaux, Adametz, and Kayser have, however, shown that, although milk-sugar is not fermentable by the ordinary yeasts, there do exist one or more forms of yeast which have the power of setting up alcoholic fermentation in this carbohydrate. These milk-sugar yeasts, as we may call them, were obtained from a dairy in which much trouble had arisen through the fermentation of the milk. The action of these yeasts on various kinds of sugar has been compared with that of ordinary high fermentation brewers' yeast, and some very interesting differences between them have been brought to light. For not only have these milk yeasts the unique property of fermenting milk-sugar, but they are also far more effective than brewers' yeast in fermenting galactose, whilst, on the other hand, they are much inferior to brewers' yeast in bringing about the decomposition of maltose. The results shown in Table (p. 937) were obtained by Kayser.

In consequence of these new yeasts giving rise to a pure alcoholic fermentation of milk-sugar, it has naturally been suggested that by means of them a sparkling and highly nutritious alcoholic beverage might be prepared on a large scale from the whey which occurs as such an abundant by-product in the manufacture of cheese. The following figures show the composition of such whey-wine, as it may be designated, and which is said to resemble cider in flavour. To increase the alcoholic strength cane-sugar was added to the whey before fermentation; whilst on another occasion the expedient of concentrating the whey before fermentation was adopted; the latter method was, however, not found promising, as the taste was thereby rendered somewhat too saline :—

	Whey and Sugar.		Whey (concentrated).
	Yeast c.	Yeast c. + (Saccharomyces apiculatus).	Yeast c.
	per cent.	per cent.	per cent.
Residual Sugar	2·92	1·17	2·37
Alcohol, by weight	2·88	3·68	3·00
Acidity	·14	·15	·60

The possible extent of such an industry may be gathered from the recent statistics prepared by Rew, and which show that 224 millions of gallons of milk are annually used in the United Kingdom for the manufacture of cheese.

This fermented whey is, of course, an entirely different product from koumiss, which is the result of several concurrent fermentations in the milk; in all probability a lactic fermentation at the outset being followed by an alcoholic one subsequently.

Fermentation of Artificial Sugars.

The question of the fermentation of different sugars by yeast has acquired a particular importance and interest since the magnificent achievement of the preparation of artificial sugars by Emil Fischer. These researches are not only of profound interest from a purely chemical point of view, but also in their relationship to fermentation phenomena, and the light which they have thrown on the constitution of the several forms of sugar. Not only has Fischer succeeded in artificially preparing the two most important natural sugars, viz., dextrose and lævulose, but he has also produced in the laboratory sugars which either do not exist in nature or at any rate have not yet been discovered there. He has indeed excelled nature in the production of sugars, for whilst no natural sugar of the glucose-type contains more than 6 atoms of carbon, Fischer has synthesised sugars containing 7, 8, and 9 atoms of carbons respectively. It would be beyond the scope of these lectures to detail the beautiful and ingenious methods by which these bodies have been built up, but the matter is of so much importance to all interested in fermentation questions, that I feel constrained to review them very briefly.

The mere production of a sugar of the glucose type is not a matter of any great difficulty, it can be accomplished in essentially the same way as alcohol is converted into aldehyde, *i.e.*, by oxidation.

$$\underset{\text{(Alcohol)}}{C_2H_6O} + \underset{\text{(Oxygen)}}{O} = \underset{\text{(Aldehyde)}}{C_2H_4O} + \underset{\text{(Water)}}{H_2O}.$$

If, instead of taking ordinary alcohol, we take glycerin, and submit this to oxidation, we obtain a true sugar, capable of being fer-

mented by yeast, and exerting the well known reducing action on Fehling solution :—

[Experiment.—Dissolve 10 grms. glycerin and 35 grms. soda crystals in 60 grms. warm water, cool down to temperature of room, and then add 15 grms. bromine. Shake: the bromine dissolves, and carbonic anhydride is evolved; the reaction is only complete in half an hour; but already after two minutes, the production of glycerose can be demonstrated. Take a portion of the liquid, decolourise with sulphurous acid, add excess of caustic soda, then heat with Fehling solution, the characteristic reduction of which at once takes place.]

The sugar thus obtained in an impure form contains only three atoms of carbon, and may be called glycerose $C_3H_6O_3$.

This triatomic sugar passes, however, spontaneously into a true hexatonic glucose :— $2C_3H_6O_3 = C_6H_{12}O_6$.

This hexatomic sugar is the starting point in the artificial preparation of the true sugars; the name of *α—acrose* has been given to it; and it is inactive towards polarised light. Before tracing its metamorphoses further, we must glance at a reaction which has proved of inestimable value in all investigations connected with the sugars, and has already taken its place beside Fehling's solution and the polarimeter in the sugar laboratory. I refer to the reaction between the sugars and the substance known as phenylhydrazine.

This substance readily enters into combination with divers sugars, forming compounds which can be easily purified, and which are particularly serviceable in the identification of different sugars. This substance, phenylhydrazine, may indeed be designated the Rosetta-stone of the sugars, having led, in the hands of Fischer, to the elucidation of the sugar-group, even as the famous stone led to the deciphering of the hieroglyphics in the hands of Egyptologists.

[Experiment.—Take solution of dextrose, add solution of phenylhydrazine hydrochloride, and sodium acetate, warm on water-bath, yellow precipitate of glucosazone.]

The following Table exhibits the value for purposes of diagnosis of these compounds :—

	Melting-point in Degrees C.	
Glucosazone	205 ..	lævorotary in glacial acetic acid.
Galactosazone	193 ..	inactive in glacial acetic acid.
Sorbinosazone	164 ..	ditto, ditto.
Lactosazone	200 ..	ditto, ditto.
Maltosazone	206 ..	ditto, ditto.
Arabinosazone	160 ..	inactive in alcoholic solution.
Xylosazone	160 ..	lævorotary in alcoholic solution.
Rhamnosazone	180 ..	ditto, ditto.
Gulosazone	156 ..	ditto, ditto.

But not only are these osazones of such importance in the diagnosis of sugars, but they have also been invaluable in the artificial synthesis of these bodies in consequence of the remarkable transformation which they undergo on treatment with strong hydrochloric acid. Thus

$$\underset{\text{(Glucosazone.)}}{C_6H_{10}O_4(N_2H.C_6H_5)_2} + \underset{\text{(Water.)}}{2H_2O} = \underset{\text{(Glucosone.)}}{C_6H_{10}O_6} + \underset{\text{(Phenylhydrazine.)}}{2C_6H_5N_2H_3}.$$

The glucosone on treatment with nascent hydrogen yields a sugar of the lævulose-type : –

$$\underset{\text{(Glucosone.)}}{C_6H_{10}O_6} + \underset{\text{(Hydrogen.)}}{H_2} = \underset{\text{(Glucose of lævulose type.)}}{C_6H_{12}O_6}.$$

Equipped with a knowledge of these changes, we can now attempt to study the Table on p. 940, which indicates the several steps which have led to the artificial preparation of the well-known sugars, dextrose and lævulose.

The beautiful symmetry of this series of reactions cannot fail to appeal to all, but no one excepting the chemist can adequately appreciate and admire the marvellous ingenuity of the design and the brilliant experimental skill demanded for its execution and accomplishment.

We now not only understand the chemical difference between dextrose and lævulose, which had previously been explained by Kiliani's formulæ :—

CH$_2$OH. CHOH. CHOH. CHOH. CHOH. CHO.
Dextrose.

CH$_2$OH. CHOH. CHOH. CHOH. CO. CH$_2$OH.
Lævulose.

But we have through Fischer's researches been supplied with the true optical isomer of dextrose, *i.e.*, a lævorotary glucose, as well as the optical isomer of lævulose, *i.e.*, dextro-rotary lævulose.

This dextro-rotary lævulose is obtained, as shown in the diagram, by fermenting the artificial and inactive fructose with brewer's yeast, in which fermentation the yeast cells single out the ordinary lævulose molecules, decomposing them into alcohol and carbonic

α-ACROSE (from Glycerose)

i-Glucosazone (by union of α-Acrose with phenylhydrazine)

d-Glucose (by reduction of *d*-Gluconic acid with nascent hydrogen)

---

acid, whilst the dextro-rotary lævulose molecules, which are an entire novelty, and of which the yeast organisms and their ancestors have no experience in the past, remain untouched by them. This phenomenon is particularly noteworthy, as being the first instance in which the capacity of yeasts to select between two optical isomers has been put to the test. Indeed, this is the first instance of optical isomerism in the sugar-group at all.

We must now turn to the second group of recent discoveries in the department of the sugars, which includes the synthesis of sugar containing more than the six atoms of carbon which we find in the natural sugars.

The fascinating problem of thus building up sugars of greater molecular magnitude, really depends upon chemical reactions of great simplicity, and which a few minutes attention will render fully intelligible.

Any of the sugars, whether of the dextrose or lævulose type, can combine with hydrocyanic acid to form an oxycyanide in the same way that ordinary aldehyde and acetone do.

$$\underset{\text{(Aldehyde)}}{\begin{array}{c} CH_3 \\ | \\ CHO \end{array}} + \underset{\text{(Hydrocyanic acid.)}}{HCN} = \underset{\text{(Oxycyanide.)}}{\begin{array}{c} CH_3 \\ | \\ H\text{—}C\text{—}(OH) \\ | \\ CN \end{array}}$$

$$\underset{\text{(Acetone.)}}{\begin{array}{c} CH_3 \\ | \\ CO \\ | \\ CH_3 \end{array}} + \underset{\text{(Hydrocyanic acid.)}}{HCN} = \underset{\text{(Oxycyanide.)}}{\begin{array}{c} CH_3 \\ | \\ C\langle\begin{smallmatrix}(OH)\\(CN)\end{smallmatrix} \\ | \\ CH_3 \end{array}}$$

These oxycyanides, by treatment with caustic alkalis, yield the corresponding oxy-acids:—

$$\begin{array}{c} CH_3 \\ | \\ H\text{—}C\text{—}(OH) \\ | \\ COOH \end{array} \quad \text{and} \quad \begin{array}{c} CH_3 \\ | \\ C\langle\begin{smallmatrix}(OH)\\(COOH)\end{smallmatrix} \\ | \\ CH_3 \end{array}$$

Applying these reactions to a typical case in the sugar-group, we will take dextrose:—

$$\underset{\text{(Dextrose)}}{CH_2OH.\ CHOH.\ CHOH.\ CHOH.\ CHOH.\ CHO.}$$

$$+ \underset{\text{(Hydrocyanic acid)}}{HCN.} = \underset{\text{(Oxycyanide)}}{CH_2OH.\ CHOH.\ CHOH.\ CHOH.\ CHOH.\ CH\begin{cases}(OH)\\(CN)\end{cases}}$$

from which is obtained the corresponding oxy-acid:—

$$CH_2OH.\ CHOH.\ CHOH.\ CHOH.\ CHOH.\ CHOH.\ COOH$$

and from this, by reduction with nascent hydrogen (sodium amalgam), is then obtained the corresponding sugar:—

$$CH_2OH.\ CHOH.\ CHOH.\ CHOH.\ CHOH.\ CHOH.\ CHO$$

containing 7 atoms of carbon, and which we may call *heptose*. From this heptose we can pass by similar reactions to a sugar containing 8 atoms of carbons, or *octose*, and from this, again, to one containing 9 atoms, or *nonose*. This is as far as the synthetical method has hitherto been carried, but there is no reason why it should not be possible to pursue the same processes even much further.

Now these substances are of more interest from a physiological than a chemical point of view, and already experiments have been made in order to ascertain the attitude of yeast towards them. The results in this direction are extremely remarkable, showing that those sugars are fermentable which contain 3, 6, or 9 atoms of carbon, whilst the remainder are, without exception, unfermentable.

In concluding this part of the subject, I may fittingly draw your attention to the magnificent collection of sugars which science has revealed up to the present time.

TRIOSE.
$C_3H_6O_3$ .. Glycerose.

TETROSE.
$C_4H_8O_4$ .. Erythrose.

PENTOSE.

NONOSE.
$C_9H_{18}O_9$ .. Mannononose.

N.B.—In the above Table *d* = dextro-rotary, *l* = lævo-rotary, *i* = inactive to polarised light.

Of the 31 sugars in this Table, all, excepting 8, are the direct result of the indefatigable zeal and genius of Emil Fischer.

Miscellaneous.

JAPANESE CERAMICS.

The French Chargé d'Affaires at Tokio says, in his last report, that the most ancient type of Japanese ceramics known is the *Kaizuka-doki*, of which specimens have been found at Omori and its environs. The articles themselves are heavy and clumsy, and the decorations, which are very primitive, are confined, in the majority of cases, to a few lines, curves, or crosses. In the porcelain known as *Iwaibe-doki* a decided improvement is shown, and the same may be said of Corean pottery. Several articles of this description of pottery, presenting the characteristics of solidity and finish, are frequently met with in the tombs of the first emperors. One of the latter, Suimin, who reigned at the earlier period of the Christian era, favoured with his patronage a celebrated Corean potter, named Koki, who came to Japan about that time. In 649 A.D. an edict of the Emperor Kotoku decreed that taxes might be paid in porcelain, and this gave a decided impetus to the production; from the tenth to the fifteenth century, however, the incessant civil dissensions kept the ceramic art in a condition of depression, from which it only commenced to recover in 1598, the year in which Hideyoshi brought back from his travels in Corea potters from that country, who established themselves in his dominions. The first attempt at exportation was made in 1646; and about seventy years later two potters, in spite of the interdiction against foreign travel, left secretly for India, where they sold considerable quantities of porcelain, which in all probability consisted of inferior Imari and Nabeshima ware. These men, however, paid for their temerity with their lives, as they were thrown into prison on their return, where they committed suicide to escape their punishment. It was only in 1842 that the export of porcelain was seriously engaged in, and the trade has continued up to the present day.

Statistics assign to porcelain the seventh place in the list of exports from Japan; but when it is considered that the articles which precede it are, for the most part, raw materials and articles of consumption, such, for example, as silk, cereals, tea, coal, products of the sea, and metals, it will be seen that porcelain holds the first place in home-manufactured articles. Mr. Hosoki, professor of the Technological School, at Asakusa, has recently pointed out, in a dealing with this particular branch of national production, the advantages that would be derived in extending the relations with North America. According to him, the States of the American Union, whose demands for Japanese porcelain have increased threefold during the last five years, are destined to become the principal export market for these articles. It is true that, at present, Japan only furnishes about two per cent. of the porcelain and faïences imported into the United States; but the opening of a canal across Central America, which will allow of goods coming directly to North American ports situated on the Atlantic, will considerably increase the trade. To keep pace with the times, Mr. Hosoki has made many suggestions and recommendations, among them being one for the substitution of carbonate of lime for wood ashes (*Isu-bai*) in the glazing of the porcelain. The Isu tree which grows at Kinshin, supplies the finest quality of this vegetable ash, but on account of the increasing demands, it is becoming rarer and dearer each year. The important element of this ash is carbonate of lime, which abounds in a natural state in many parts of Japan, and at a fifteenth part of the cost. Experiments which have recently been made at the Technological School of Asakusa, have proved that its use would diminish, by two-thirds at least, the cost of glazing, and would effect, out of the 100,000 piastres annually expended in the purchase of this vegetable ash, a saving of about 70,000 piastres. The porcelain workers would also reduce their expenses very considerably by substituting charcoal for the pine wood now used for the baking, and also by a more general adoption of improved machinery. Mr. Hosoki is of opinion that the abundance of kaolin throughout the empire, and the artistic aptitudes of the Japanese people, will certainly contribute to render the ceramic industry one of the chief sources of wealth in the country. The Mino porcelain consists of twenty-six different varieties; the best known is the blue and white, which has the largest sale on the home markets and in China. Unfortunately, the necessity of producing in large quantities and at a cheap rate has adversely affected the value of this article. The sale abroad of Kutani porcelain and faïences realises annually about 180,000 piastres, but here, again, the quality has deteriorated. In 1888, the latest year for which the statistics are available, the number of factories engaged in making porcelain was 4,788; the number of workmen employed, 26,762. The articles made numbered over 126,000,000, and the value exceeded 2,000,000 piastres.

RUSSIAN TRADE ASSOCIATIONS.

There are only two kinds of association in Russia for labour purposes—(1) the Association of Artisans and (2) the Artels. The artisans have a particular organisation of their own, and their own especial institutions, for the purpose of safeguarding their interests. Her Majesty's Secretary of Embassy at St. Petersburg says that in that city their number amounts to about 60,000, and they represent one-eleventh of the entire population. These associations in St. Petersburg are about eight in number, and comprise about twenty-five different trades. Each association has its own bureau, composed of three representatives and a secretary, which forms its executive committee. A list is kept containing the names of all the members of the association, their families, and all the necessary information respecting their station. The committee is charged with the duty of settling all differences that may arise, fixing penalties, distributing the common funds, helping the poor and sick, and exercising control over the work in the workshops, the foremen, and apprentices. The committee is obliged to execute the orders of another body, which represents the whole of the artisan class, and which is composed of a president, the heads of all committees, and the delegates from every association. The president of this central committee has to control the acts of the smaller committees, he has to visit the workshops, take measures to preserve order and discipline, inspect the registers, see that the apprentices are well treated, and that relief is granted to the sick, the widows, and orphans. All the members of each association meet once a year, and oftener if necessary, to elect their executive committees, settle the amount each incoming member must pay, and discuss the budget. The executive committees also meet together once a year to discuss the affairs which touch the interests of the whole body of artisans. The "artel" is the only other form of association to be met with in Russia. It is peculiar to the country, and is to be found in every branch of industry. It is based rather on local customs than any special regulations. The primitive form of the institution is an association of workmen who live together, feed together, and work together, and on the termination of each piece of work divide the profits amongst themselves. Labour, therefore, was the primary motive of the formation of the artel, which as soon as capital made itself felt and workmen began to make engagements with a contractor, and receive from him monthly wages, was destroyed. Like the Mir or Commune, the members of the artels have an equal share in the profits, and stand under the direction and authority of a foreman or elder. In the larger towns the artels are of a much more complex kind, possessing a large capital and pecuniarily responsible for the acts of the individual members. Such, for instance, are those of the bank porters, who have unlimited opportunities of stealing, and are often entrusted with the care and transport of enor-

mous sums, but the banker has no cause for anxiety because he knows that if any defalcation occurs it will be made good to him by the artel. The artel being responsible for the individuals of which it is composed, is very careful in admitting new members, and a man when admitted is closely watched, not only by regularly constituted office bearers, but also by all his fellow members who have an opportunity of observing him. It is not surprising therefore, that this kind of artel is to be met with in a great number of industries in Russia, so that the term arteltchick (member of an artel) now stands for that of a clerk. There are various sorts of artels; they are to be found in the country, where the peasant, who is too poor to cultivate purchased or leased lands, forms with other peasantry in the same condition as himself, an artel, and cultivate it in common, dividing amongst themselves the profits of their labour. The oldest is generally chosen as chief, and the work is subdivided according to each man's physical force. There are artels of shepherds who are hired by the commune, but generally paid in kind. Everything that they receive is put by into one common store, and then sold. There are artels in the postal service, among peasants who furnish horses and vehicles, and artels of itinerant carpenters who, however different their wages may be, divide everything in common among themselves. Generally speaking, the artels are divided into four distinct classes:—(1) Industry, (2) credit, (3) food, and (4) insurance. The artels for credit are somewhat rare, owing to the fact that the Russian workman seldom puts by any money, and when he does is deterred, by reasons of fear, from lending it to any association. On that account the Government, the local authorities, landed proprietors and owners of factories, have interested themselves in this direction by advancing capital for the purpose of forming savings' banks.

THE ITALIAN SALT MONOPOLY.

A report has recently been prepared for the *Bulletin de Statistique et de Legislation Comparée* by M. Castorina, an Italian Government official, upon the subject of the salt monopoly in Italy. It appears from this report that the Italian Treasury obtains annually a revenue of about £2,080,000 from this source. The State owns ten salt mines or marshes, those of Cervia, Comacchio, Corneto, Tarquinia, Lungro, Margherita di Savoia, Portoferraio, Salsomaggiore, San Felice, Cagliari, Carloforte de Sardaigne, and Volterra. The salt works of Salsomaggiore, San Felice, Cagliari, and Carloforte de Sardaigne are conceded to private persons or companies, who pay an annual sum to the Government. The method of production employed in the salt works varies according to district and the nature of the product. At Lungro, where rock-salt abounds, it is worked with the pick; but this system could not be adopted in places where the layers of salt, unequally distributed in the subsoil, would not bear the expenses of the working. At Salsomaggiore, as well as at Volterra, the water which filters through the soil penetrates through the salt beds, dissolves them, and falls, loaded with salt, into wells, from which constant supplies are drawn. The salt obtained in this manner, from salt water evaporated by the action of fire, is much superior to the sea salt. The other State salt works are all situated on the sea coast, and the methods of production only vary in very slight proportions. In salt marshes, it is of importance that evaporation should be obtained by natural heat, and as rapidly as possible. The salt marshes which are farthest south are much the best, and in those districts where a clear sky and dry air are not favourable to the action of the solar rays, the working is carried on with some difficulty, and it frequently happens that rain comes to spoil the harvest before the salt is completely deposited. Italy is very little behind other countries from the point of view of the abundance and purity of the product. The cost price of the salt varies between a maximum of 2s. 6d. and a minimum of 5d. per 100 kilogrammes. The salt works of Cervia are situated in the province of Ravenna, and are about 5,880 metres long and 2,130 metres wide. The production of salt at Cervia amounted, during the year 1890-91, to about 19,000 tons. The Comacchio salt works are about four kilometres from the town of the same name, near the mouths of the Po, and not far from the port of Magnavacca. The working dates from an early period, and it was in 1810 that the Comacchio salt commenced to supply the requirements of Venetia, of Lombardy, and even of central Italy, where it was sent by river, this being the surest and most economical method of transport. In 1885 these salt works only produced about 10,000 tons, but this quantity has since increased to 27,000 tons, owing to the improvements effected in the basins. The salt works of Corneto Tarquinia, situated on the coast of the Mediterranean, a few miles to the north of Civitavecchia, date back to the year 1805. These works are among the most productive in Italy, the average yield per hectare being three times greater than that of the Cervia works, and about equal to that of Comacchio. The annual product is about 5,000 tons of good salt for consumption. The mineral salt works of Lungro, a small commune of Castrovillari, in the province of Cosenza, situated about 410 metres above the level of the sea. The surface of this mine worked is about 32 acres in extent, divided into five series of excavations according to the depth of the workings. The production, which naturally varies with the richness of the beds, amounted to over 6,000 tons in 1890-91. The Margherita di Savoia works are situated on the borders of the Mediterranean, on the south-eastern point of the province of Foggia, and the quantity of salt produced in 1890-91 exceeded 43,000 tons. The

Portoferraio works for the production of sea salt are in the neighbourhood of the place from which they take their name, and were established by the Grand Duke of Tuscany, with the double object of improving the marshy lands, and of procuring work for the natives of the Isle of Elba. The product is about 3,000 tons annually. The Volterra works are at the west of the town of the same name. This establishment is fed by the water of certain natural wells, known as *mojes*, from which the salt water is continually flowing. The salt works of Cagliari and Casloforte, in Sardinia, are, as regards the quantity and quality of their products, the most important in Europe. The first is situated at a distance of about three miles from Cagliari; a narrow canal of about 600 or 700 metres in length connects it with a large pond, which in its turn communicates with the sea. This pond constitutes the true wealth of the Cagliar salt works. Of somewhat minor importance are the works of Carloforte, and the total product of Cagliari and Carloforte amounts on an average to about 130,000 tons. The Salsomaggiore works are about nineteen miles from Parma and five from Borgo-San-Domino, and the quantity of salt produced is only about 500 tons annually, which is principally used for salting provisions. The San Felice works are about six miles from Venice, and are some of the largest in the kingdom, although they only produce about 7,000 tons of salt annually.

THE CULTIVATION AND PREPARATION OF VANILLA.

Notwithstanding the various preparations that have lately been put upon the market as substitutes for the vanilla for flavouring purposes, a great deal of attention is still directed to the cultivation of the plant, and the preparation of the fruits for commercial purposes. Perhaps the most recent and formidable rival in the cultivation of vanilla is Fiji, from whence some good samples have more than once been received. The first consignment sent to London brought from the consignees a very congratulatory report on the prices realised, namely, 22s. 6d. per lb. for three-fourths of the consignment, and 21s. 6d. for the remaining fourth. The consignees further say that "unless the quality had been very satisfactory no such price could have been obtained, and if further consignments are up to the quality now sent in, we can say that Fijian vanillas will command a good price and a great sale. Speaking from an experience of nearly forty years, during which we have handled a considerable quantity of vanillas, we can unhesitatingly say that the quality of that sent here is equal to any vanilla grown in the Mauritius or elsewhere. The beans are plump and well cured, and are beginning to throw out splendid crystals. In future consignments it will be necessary to sort the vanillas and tin them according to lengths, and to take care not to pack the tins too closely."

In connection with the subject of the preparation of vanilla for market, one of the most striking departures from the ordinary mode of drying the pods seems to be that of keeping them moist or rather wet, for some sample pods have recently been received in London preserved in alcohol. They are described as of fine appearance and good aroma, though, of course, partly exhausted by the action of the spirit, which, it has been suggested, will probably be sold with the beans. It is said "that by placing the pods in alcohol when freshly gathered, a much more fragrant tincture is obtained than by exhausting the cured beans purchased in Europe."

Obituary.

Duke of Sutherland, K.G.—By the sudden death of the Duke of Sutherland at Dunrobin Castle, on Thursday, 22nd inst., the Society of Arts loses a prominent member of nearly 40 years standing. He was elected in 1853, and filled the office of vice-president in the years 1864-65 and 1879-82. It is not necessary here to give particulars of the duke's life, which are fully described in the daily papers, further than to note that he was born in 1828, and succeeded his father, as third Duke of Sutherland, in 1861. Of the duke's occupations as a landowner, the writer of the obituary notice in *The Times* says:—"There are two spheres of work in which he made for himself a reputation, which may quite fully be described as unique. They were the reclamation of waste lands and the extension of railways and railway traffic in the northern counties of Scotland."

Dr. G. D. Longstaff.—George Dixon Longstaff, M.D., who died at his residence, Butterknowle, Wandsworth, on Friday, 23rd inst., in his 94th year, had been a member of the Society of Arts since 1855. He graduated M.D. at Edinburgh University in the year 1828, where he was for some time assistant to Dr. Hope, Professor of Chemistry. In that capacity he is said to have been the first teacher of practical chemistry in this country. He practised as a physician at Hull, and then spent some years in America. Upon his return to England he interested himself in mercantile affairs. Dr. Longstaff was an active supporter of Wilberforce's anti-slavery movement. He was one of the founders and a vice-president of the Chemical Society of London, and for many years he was chairman of the Royal Maternity Charity. He had resided in the parish of Wandsworth for upwards of 50 years, and was one of the first members of the Wandsworth District Board of Works. Dr. Longstaff was an occasional contributor to the *Journal*, and he held the office of treasurer to the Society from 1863 to 1865.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Chicago Exhibition, 1893.

REPORT ON THE PROGRESS OF WORK.

The following report on the progress made in the work and preparation for the Columbian Exposition at Chicago has been transmitted to the Foreign Office by Colonel Hayes Sadler, H.B.M. at Chicago. It is dated September 1, 1892, and gives a very full account of the progress made to that date :—

Appearance of the Grounds.

Now that the principal constructions of the World's Columbian Exposition approach completion, the exterior of nearly all being finished, while the grounds around them are already, in a great measure, laid out, it is possible to form a general idea of the effect which will be presented when the Exhibition opens to the public on May 1 next year. The beauty of the scene can scarcely be exaggerated, and when the object and size of the immense buildings, which are all of classical design, with the vast extent of ground they occupy, are considered, it is difficult to imagine a more perfect arrangement than has been planned. A peculiar feature is the harmony which unites the various buildings, designed by different architects, into one artistic panorama; and to this the site on the borders of Lake Michigan lends a natural perfection. Lagoons and canals everywhere intersect the grounds, and the irregularity of outline of these water spaces, and of the wooded island in their midst, contrasts charmingly with the long straight lines of architecture which are thus thrown with somewhat irregular disposition. The effort so successfully carried out will, undoubtedly, exercise a powerful influence on artistic feeling in the country; and even were no exhibits of matured excellence to be seen within, the buildings cannot fail to stimulate the development of taste, and guide towards perfection in art in the New World. The main object of the Exhibition is far more material, but to this nothing will be lost by added charm of artistic beauty and grandeur. The extent of the grounds and size of the buildings have been described in a previous report. Some idea of the vastness of the undertaking may be formed by comparison with the Exhibitions of Paris, in 1889, and of Philadelphia, in 1876, as follows :—

		Paris.	Centennial.	Chicago.
Area of grounds	Acres	238	284 49	633
„ buildings	„	75·5	70·08	142·12
Cost of „	Sterling £	720,752	1,037,966	1,457,206

The approximate exhibit space at Philadelphia was 4,323,330 square feet, and at Chicago it is estimated at 9,138,888 square feet.

Progress in Construction.

The work of construction progressed satisfactorily during the early part of the year, there having been few days when operations were checked by severe weather, but it was much retarded by heavy rains in May and June. The rainfall in June was 10·58 inches, and work was interrupted for 18 out of 30 days, foundations were flooded, and the underground work of laying pipes suspended, while some slight damage was done by severe storms of wind. When possible, the full force of 7,000 men was employed, but not so much work was accomplished during those two months as had been counted on, and at the end of June the two great buildings, the Manufactures and Liberal Arts and the Mines and Mining, presented a very unfinished appearance. In July, however, on a change of weather, extra hands were put on, and such progress was made that no fear is now entertained but that these buildings also will be completed in time for the dedication on October 21.

The condition of the principal buildings at the end of July was as follows :—

In the Administration Building the construction is complete, and all staff work placed. The dome framework is erected and covered in, but gilding and decoration has not yet commenced. The statues are being cast for the interior, many for the exterior being finished, though not yet in place.

The Mines and Mining Building is com-

plete, but it will probably receive another coat of colouring.

The Electricity Building is finished as far as ironwork and woodwork are concerned. The staff on the north and east sides is placed, and on part of the west side.

The main part of the Transportation Building is practically complete, but the Annex has yet to be built.

The Horticultural Building is entirely finished, with the exception of some of the sculptured groups to be placed outside.

In the Women's Building little remains to be done but interior decoration. The outside sculpture work on the pediment is progressing.

In the Fisheries Building the imitation Spanish tile roofing is all in place; the concrete work of the aquarial tanks and fountain is nearly finished. The ornamental staff work outside and on the north and south entrance loggias is all complete.

In the Art Gallery the iron contractors have finished their work on the dome; nearly all the masonry work is done, and nearly all work on the building completed. Plain and ornamental staff on the north side and entrance on the east end is placed, and three-quarters of the ornamental and half of the plain staff placed on the south side and entrance.

In the Manufactures and Liberal Arts Building all the 22 large trusses are up, and the diagonal and smaller trusses placed on the south end. The traveller will shortly be moved to put up smaller trusses on the north side. Skylights in the wood-covering are in course of placing; where there is no skylight the wood will be covered with canvas. The side trusses are placed on the west and east and partly on the south sides, and the roofing of the naves is erected. The staff is placed on the north-east and north-west pavilions, wood and staff work progressing in other parts. The amount of steel work erected to end of July was 9,539,000 lbs. out of 12,000,000 lbs. required; lumber, 13,784,288 feet, out of a total required of 17,000,000 feet. The central hall of this building is 1,280 feet by 380 feet; a nave 107 feet wide runs round the whole building, and the entire length of the building, with the strip running between the central hall and the nave, is 1,687 feet, and the width 787 feet. The highest part of the dome is 245 feet. There are 4,000,000 feet of lumber in the foundation, not including the piles, and 3,000,000 feet (200 cars loads) in the floor. It is three times the area of St. Peter's at Rome, and four times as large as the Colosseum.

In the Machinery Hall the iron work on main buildings is complete, except the central dome. Carpenters are sheathing the east end and working on the roof. All the staff work is placed on the north side of the Annex, and three-quarters of the ornamental staff placed on the west end. Groups of statuary for the outside of main buildings are being made, and some figures are in position on ridge line of roof.

The Forestry Building is roofed and nearly finished, the rustic colonnade is almost completed, and the rustic trimmings are all in place on both interior and exterior of window and door frames. Split oak shingles are now being placed on the roof.

The main Agricultural Hall is done except interior trim and placing statuary. Some statues have already been placed and decorative fresco work started in the loggias. The roof joists of the Annex have been set, structure entirely sheathed in, and staff work advancing; canvas and metal roofing finished.

The Dairy Building is wholly finished.

With the exception of manufactures and machinery, all the above buildings are roofed and windows glazed, and comparatively little remains to be done but interior decoration. All will be coloured with a light tint of old ivory or cream, varying somewhat in the different constructions; the tinting, which is finished on some of the buildings, is effected by means of a liquid spray, composed chiefly of oil and colouring matter. The statues are moulded of staff (on a light framework of wood), the same material as is used for covering the outside of all the buildings.

The central dome of the Government Building is sheathed in, and the corrugated iron covering is being replaced. All the building is covered with staff and practically finished, except interior trim. The estimated cost, with the Annexes for the army and weather bureaux, is £78,577, and the whole expenditure contemplated by the Government is £300,000.

The Illinois State Building is an imposing structure. Rough work is all done except on the dome, the plastering of the exterior nearly finished, exterior covering being placed on all sides of the building. There are 22 other State buildings in course of construction, some of them being far advanced, namely, Maine, New Hampshire, Massachusetts, Rhode Island, Connecticut, New York, Pennsylvania, Delaware, Maryland, Michigan, Wisconsin, Indiana, Ohio, Colorado, Cali-

fornia, Nebraska, Kansas, Iowa, Missouri, West Virginia, Minnesota, and Montana. These are all grouped at the northern end of the park on the separate ground allotted them, and are of great variety of design; many are important buildings, and will present a charming effect.

The following foreign countries will erect buildings:—Great Britain, Canada, Ceylon, Germany, Japan, Argentine Republic, Austria, Brazil, Costa Rica, Colombia, Chile, Ecuador, France, Guatemala, Hayti, Mexico, Nicaragua, Norway, Sweden, and the Hawaiian Islands, also the State of Rio, Brazil. Others may yet decide to do so.

The British Building was the earliest foreign construction commenced, the first pile having been driven three months since on the small but beautiful site allotted on the shore of Lake Michigan, to the north-west of the United States Building. The walls are constructed to the first floor, and flooring laid, but otherwise not much progress has been made, work having been delayed owing to non-arrival of detailed plans, and delay in delivery of material. Plans for the German, Ceylon, and Swedish Buildings have been accepted and ground allotted. The Ceylon construction will be in the form of a Ceylonese Court; the Swedish Building, of the old Swedish Cathedral style, is to be constructed entirely in Sweden, and shipped in sections, and will cover 12,000 square feet.

[*To be continued.*]

Proceedings of the Society.

CANTOR LECTURES.

RECENT CONTRIBUTIONS TO THE CHEMISTRY AND BACTERIOLOGY OF THE FERMENTATION INDUSTRIES.

By Percy F. Frankland,
Ph.D., B.Sc.(Lond.), F.R.S., Professor of Chemistry in St. Andrew's University, Dundee.

Lectnre IV.—Delivered May 23, 1892.

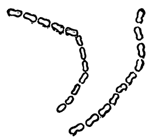
Bacterial Fermentations.

The fermentation phenomena induced by yeast, although of such enormous importance from a practical, commercial, or pecuniary point of view, are comparatively tame and uninteresting from the theoretical side, as compared with the varied changes which result from the vital activity of other micro-organisms. Whereas, in the case of yeasts, the number of substances acted upon is extremely limited, including only a few of the sugars, and the products of fermentation almost confined to alcohol and carbonic acid, in the fermentations induced by bacteria, on the other hand, not only are the substances attacked immensely more numerous, including both organic and mineral bodies of the most varied composition and constitution, but the products of fermentation are also greatly more diversified.

A great many of the investigations of these bacterial fermentations were made before the introduction of those exact methods for the study of micro-organisms, to which I referred in my first lecture, so that they require practically in all cases a reinvestigation on a more sound basis. Much has already been done in this direction, but it is a mere fraction of what still remains.

Of these bacterial fermentations, the one which has longest been industrially recognised is the acetic or vinegar fermentation, the exciting cause of which was found by Pasteur, in 1864, to be an organism which, owing to its forming a skin on the alcoholic liquid, he named "mycoderma aceti," and which formerly had been known as "Flowers of Vinegar." He further showed that this microbe per-

Fig. 18.



Mycoderma aceti.

forms the function of an oxygen-carrier in the reaction, and that if its vitality is impaired, aldehyde, instead of acetic acid, makes its appearance, whilst, if the fermentation is allowed to continue after the whole of the alcohol has been transformed, then the acetic acid itself falls a prey to the oxidising power of the organism, and is converted into carbonic acid and water.

Our knowledge of this remarkable and important fermentation has recently been greatly extended by Adrian Brown, who has shown that normal propyl alcohol can be oxidized by the mycoderma aceti to propionic acid, whilst methyl alcohol, isoprimary butyl alcohol, and amyl alcohol, are all unaffected by it.

This mycoderma aceti is also able to exert its oxidising powers on some polyhydric alcohols and on some of the sugars; thus,

with glycol it forms glycollic acid; with glycerin, on the other hand, the oxidation is complete, carbonic acid and water being formed; with mannite, lævulose is formed; whilst with dextrose the result is gluconic acid. On cane-sugar it has no action, nor on dulcite or erythrite.

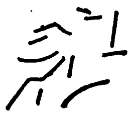
Brown has also extended his investigations to the origin of the tough gelatinous mass which is often found on the vessels employed in the manufacture of vinegar, and which generally goes by the name of "vinegar plant," or "Mother of Vinegar." This material is found to be cellulose, and is produced by an organism closely resembling the mycoderma, but differing in the possession of the distinctive property of producing this jelly-like substance from either dextrose, lævulose, or mannite, but especially from lævulose. These transformations by the *bacillus xylinus*, as this organism has been named, from its power of building up woody fibre or cellulose, are of great theoretic interest.

Another very familiar and ancient fermentative change, which is much feared in many industries, is the so-called lactic fermentation, which takes place so readily in milk, and which consists in the conversion of the various kinds of sugar—generally milk-sugar—into lactic acid. This has also been the subject of several recent investigations. In the ordinary lactic fermentation induced by the bacillus, which has been very thoroughly investigated, more especially by Pasteur, Lister, and Hueppe, the lactic acid formed is inactive towards polarised light. Quite recently, however, another lactic fermentation has been discovered by Schardinger, induced by a totally distinct organism, and the lactic acid formed in this case is active, but, unlike the active lactic acid found in muscular tissue, it is lævorotary, instead of dextrorotary. On mixing equal quantities of these two active lactic acids in solution, the ordinary inactive lactic acid is obtained. The optical isomers predicted by theory, and of which the dextrorotary isomer has been well known since the classical researches of Wislicenus, are now completed through the discovery of this fermentation product. In fact, all three optical isomers are obtainable by fermentation, the lævorotary form by Schardinger's organism, and the dextrorotary one by an organism found by Nencki and Sieber.

Chemical science is, in fact, continually becoming more and more indebted to the work of micro-organisms, which are becoming indispensable reagents in the chemical laboratory, as it is only by their intervention that many substances are accessible. Their utility to the chemist depends generally upon their remarkable power of differentiating between closely similar substances. We have already noticed how differently the several members of the sugar-group are affected by yeasts, some sugars undergoing ready fermentation by some particular form of yeast, whilst other sugars obstinately resist such decomposition. Similar phenomena of an equally remarkable character occur in connection with the bacterial fermentations.

Of this power of differentiation possessed by micro-organisms, I will bring before you an example which has recently occupied much of my attention in connection with a fermenting organism which I discovered some years ago, and to which I have given the name of *Bacillus ethaceticus*, in consequence of its decomposing a number of substances with formation of ethyl alcohol and acetic acid as the principal products.

FIG. 19.



B. ETHACETICUS (Percy Frankland).

The caprice of this bacillus was first manifested in its attitude towards two substances which are both chemically and physically very closely allied, viz., mannite and dulcite. Thus:—

	Mannite.
Occurrence	Numerous plant juices.
Taste	Sweet.
Melting-point	166° C.
Crystalline form	Large rhombic prisms.

	Dulcite.
Occurrence	Numerous plant juices, but less frequently.
Taste	Sweet, but less so.
Melting-point	188° C.
Crystalline form	Large monoclinic prisms.

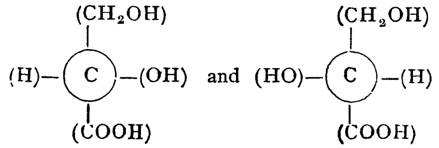
Chemically they are still more similar, for one and the same formula has to do duty for both of them, thus:—

$C_6H_{14}O_6$ or $CH_2OH.\ CHOH.\ CHOH.\ CHOH.\ CHOH\ CH_2OH.$

Under these circumstances, it might have been anticipated that micro-organisms would adopt much the same attitude towards each of these substances, but, as a matter of fact, they distinguish between these two substances

with the greatest readiness and promptitude. The *Bacillus ethaceticus*, for instance, sets up a vigorous fermentation in a suitable solution of mannite, whilst it refuses to have anything to do with the dulcite under the same circumstances.

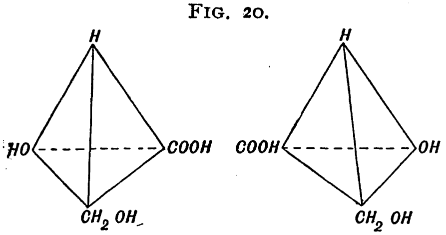
But far more strikingly is this selective capacity displayed on introducing the *Bacillus ethaceticus* into a solution of calcium glycerate, in which it sets up a fairly vigorous fermentation, which comes to an end in about a fortnight. At the close of the fermentation, about one-half of the glycerate is found to have escaped decomposition; but whilst the calcium glycerate, before fermentation, had no action on polarised light, that which remains after fermentation, is found, on examination with the polariscope, to be strongly lævorotary. Now, glyceric acid is one of those substances which chemical theory leads us to believe is composed of an equal number of dextrorotary and lævorotary molecules, combined together so as to form an inactive body—



OPTICAL ISOMERS OF GLYCERIC ACID.

The isomerism of these two glyceric acids is more easily understood by reference to the following geometrical figures, in which the particular atom of carbon, which in the above figures is surrounded with a circle, is represented by a tetrahedron, the four different groups with which it is connected being attached at the solid angles. It will be seen that these four groups can be arranged round the tetrahedron in two distinct ways (as in the figure), so that the two tetrahedra cannot be superposed so as to make the several groups coincide; the two tetrahedra are in fact symmetrical but not superposable. This theoretical conception of the arrangement of the atoms in optically active isomers was originated by Lebel and Van't Hoff in 1874, and has been of immense service in the investigation of the sugars and other bodies in which such isomerism occurs.

FIG. 20.



TETRAHEDRAL MODELS, REPRESENTING OPTICAL ISOMERISM OF GLYCERIC ACID.

The *Bacillus ethaceticus* has the sagacity necessary to distinguish between the molecules of these optical isomers which are combined in the ordinary inactive glycerate, and destroys the dextrorotary molecules by fermentation, whilst it leaves the lævorotary molecules untouched.

This lævorotary calcium glycerate crystallises in beautiful monoclinic prisms, which exhibit hemihedral faces, whist the ordinary inactive salt is not obtainable in a strikingly crystalline form at all.

A number of derivatives of this new active glyceric acid have recently been prepared in my laboratory, and their rotatory power determined :—

DERIVATIVES OF ACTIVE GLYCERIC ACID.

Formula.	Specific Rotation. $[\alpha]$ D
$(C_3H_5O_3)_2$ Ba + $2H_2O$	— 9°
$(C_3H_5O_3)_2$ Sr + $3H_2O$	—10
$(C_3H_5O_3)_2$ Ca + $2H_2O$	—12
$(C_3H_5O_3)_2$ Cd + $1\frac{1}{2}H_2O$	—14
$(C_3H_5O_3)_2$ Zn + H_2O	—22
$(C_3H_5O_3)_2$ Mg + H_2O	—18·5
$C_3H_5O_3$ Na	—16
$C_3H_5O_3$ Am	—20
$C_3H_5O_3$ K	—15
$C_3H_5O_3$ Li	—20·5
$C_3H_5O_3$ Me	— 4·8
$C_3H_5O_3$ Et	— 9·2
$C_3H_5O_3$ Pr(n)	—13·0

All these substances owe their discovery to the idiosyncrasy of my *Bacillus ethaceticus*, which leads it to consume the dextrorotary and to reject the lævorotary calcium glycerate.

FERMENTATION OF INDIGO-BLUE.

In connection with bacterial fermentations, we may glance for a moment at one which has long been industrially employed in a very interesting manner in the art of dyeing.

Amongst the natural dye-stuffs, there is none enjoying a higher reputation, both on account of the fastness and the beauty of the colours obtainable from it, than indigo. There is, however, a peculiar difficulty in the way of applying the material as a dye in consequence of its insolubility in water and other liquids available for dyeing purposes.

But although the indigo-blue itself is insoluble in water, it can easily be converted into a colourless and soluble substance known as indigo-white, by the application of suitable reducing agents. The fibres, &c., to be dyed can then be impregnated with a solution of this indigo-white, and on subsequently exposing them to the air, the indigo-blue is generated on the fibre by oxidation of the indigo-white.

Now this reduction of indigo-blue to indigo-white for the purpose of dyeing was, until recently, invariably effected by a fermentation process carried on in what is known as the indigo-vat.

The suitable medium for this fermentation is secured by mixing the following materials :—

COMPOSITION OF INDIGO FERMENTATION VAT.

Wood Vat.

Indigo	15 kilos.
Woad	300 ,,
Bran	10 ,,
Madder	2—5 ,,
Slaked lime	12 ,,

Tank of water 2 metres wide by 2 metres deep. This is the vat most commonly used in Yorkshire for woollen dyeing.

Potash Vat.

Indigo	10 kilos.
Madder	2—5 ,,
Bran	2—5 ,,
Carbonate of potash	10—15 ,,

Made up with water in similar tank.

The organism which brings about this reduction of the indigo-blue to indigo-white has not yet been either isolated or scientifically investigated; the reduction is, however, generally supposed to be effected through the agency of nascent hydrogen generated in the fermentation, and if this is the case, there should be many micro-organisms capable of bringing about the result, hydrogen being one of the products in a number of fermentations. I am at present engaged in investigating the nature of this fermentative process.

[Experiment.—Demonstration of the indigo-vat dyeing of cotton.]

BACTERIA CONNECTED WITH AGRICULTURE.

By far the most important changes resulting from bacterial life, which have been brought to light through recent scientific research, belong to the domain of agriculture, which we must indeed now regard as the most extensive and chief of the fermentation industries.

The recent investigations in this department have centred round what is undoubtedly one of the most important, and, at the same time, perhaps the most mysterious of the elements, viz., nitrogen, which, though indispensable to all forms of life, is characterised by such apparent inertness in the free state. I say apparent inertness, for we shall presently see that recent discoveries have forced us to greatly modify our views on this particular point. To farmers the question of nitrogen is all important, and we find even the most uneducated rustics with the word nitrogen on their lips.

It is with the nitrogen of the soil that we are more especially concerned this evening.

It is generally admitted, at the present time, that one of the most important plant foods in the soil is nitric acid; and scientific agriculturalists inform us that, if a soil were utterly destitute of this material, it would be incapable of growing the barest pretence of a crop, either of corn, or of roots, or of grass, even if the soil were in other respects of the most superb texture, however favourably situated, however well drained, tilled, and supplied with the mineral ingredients of plant-food, such as potash, lime, and phosphoric acid.

Notwithstanding the commanding importance of this substance, nitric acid, to vegetation, it is present in ordinary fertile soils in but little more than homœopathic doses; indeed it generally requires the most delicate chemical tests to demonstrate its presence at all.

[Demonstration of the presence of nitric acid in 1 lb. of garden soil by means of diphenylamine test.]

Thus in fertile soils there may be under some conditions as little as one part of nitrogen as nitrate, in 1,000,000 parts by weight of soil, and often less than 10 parts, whilst sometimes again the proportion may be as great as 100 parts of nitrogen in the form of nitrate in 1,000,000 parts of soil.

That such minute quantities of nitric acid are present in soil is due mainly to two causes; firstly the very soluble character of the nitrates, which occasions their being easily washed away by the rain; and secondly to the facility with which they are assimilated by plants, and which results in their being rapidly removed by vegetation. If rain and vegetation are excluded, the proportion of nitric acid, it has long been known, can be greatly increased in the soil. The soil, in fact, under ordinary circumstances continuously generates this nitric acid from the various nitrogenous

manures which are applied to it, and it is in the form of nitric acid that the nitrogen of manures principally gains access as nutriment to the plant.

Already Pasteur, in the year 1862, had suspected that this production of nitric acid in the soil was the work of micro-organisms, but it was not until 1877 that this was actually proved to be the case by two French chemists, Schloesing and Müntz. These investigators demonstated that the production of nitric acid, or process of nitrification, as it is commonly called, is at once arrested by all those materials which have the property of destroying micro-organisms, and which we call antiseptics,. whilst, similarly, the process is stopped by heat and all other influences which are known to be fatal to life in general. The vital nature of the nitrification process was confirmed by several others, without, however, coming much nearer the important problem of determining and isolating the particular micro-organism responsible for the change.

Perhaps the most important advance in this direction was made by Dr. Munro, who, in 1886, showed that this process of nitrification could take place in solutions practically destitute of organic matter, which amounted to the statement that the vital activity of the bacteria of nitrification could be maintained without nutriment of an organic nature. Although this discovery was new as regards the bacteria of nitrification, it was not novel as regards some other forms of microbes; for, in 1885, I had already myself shown that some micro-organisms can actually undergo enormous multiplication, even in distilled water:—

Multiplication of Micro-organisms in Distilled Water.

Hours after introduction of Micro-organisms.	Number of Micro-organisms found in 1 c.c. of water.
0	1,073
6	6,028
24	7,262
48	48,100

When I took up the subject of nitrification, in conjunction with my wife, in the autumn of 1886, I determined to make use of this remarkable property possessed by the nitrifying organisms of being able to flourish in the absence of organic matter, thinking that, in this way, it might be possible to achieve a separation of the nitrifying organisms from other forms, which can only grow if organic food materials are supplied to them.

The solution, which we employed for encouraging these nitrifying organisms to the exclusion of other forms, had the following composition:—

Composition of Solution Employed for Nitrification.

Ammonium chloride....	·5 grm.	In 1,000 c.c. of distilled water.
Potassium phosphate ..	·1 "	
Magnesium sulphate....	·02 "	
Calcium chloride	·01 "	
Calcium carbonate......	5·0 "	

In a purely mineral solution of this composition we carried on the nitrification over a period of upwards of four years, as shown in the following Table:—

Experiments on Continuous Nitrification in Mineral Solutions.

Generation.	Date of inoculation.	Quantity taken for inoculation.	Date when nitrification was first observed.
I	9 5 1887	Original garden soil	20 5 1887
II	25 6 "	3 needle loops from I	30 6 "
III	1 7 "	" " II	7 7 "
IV	14 7 "	" " III	23 7 "

But although this continuous cultivation of the soil-organisms in a medium free from organic matter led to the elimination of a number of forms foreign to the nitrification process, it did not lead to a pure culture of the nitrifying organisms, for several other forms also persistently maintained themselves in this mineral solution. Various considerations, however, led us to the conclusion that the nitrifying organisms probably differed from the other forms which were still present along with them in being unable to grow on ordinary gelatin-peptone, for every attempt to isolate a nitrifying organism by gelatin-plate cultivation proved fruitless.

It became necessary, therefore, to fall back on what I described in the second lecture as the "dilution process." For this purpose one of these nitrifying solutions was enormously diluted, and from this diluted liquid small portions were taken out, and each of these fractions was introduced into a separate ammoniacal solution of the same composition as that already indicated. In some of these solutions thus inoculated, nitrification took place, showing that the nitrifying organism had been introduced, in others there was no nitrification showing that the inoculation had not conveyed a nitrifying organism. Further, on examining those solutions which had nitrified, it was found that most of them contained organisms growing on gelatin, whilst one, although it had nitrified, yielded no growth whatsoever on gelatin, whilst under the microscope it was seen to contain an abundance of bacteria having the form shown in the diagram.

FIG. 21.

NITROUS FERMENT (Percy Frankland).

These results of ours were published in March, 1890, and about a month later there appeared in the "Annales de l'Institut Pasteur" a communication by M. Winogradsky, announcing the separation of a very similar, if not identical, nitrifying organism; whilst a few months latter again a separation of a similar organism was made by Mr. Warington.

The method of isolation adopted by Winogradsky was different from ours, although likewise based on the incapacity of this organism to grow on gelatin. Pouring plates of a nitrifying solution, he allowed the colonies to develop; but having found, by previous trial, that none of these belonged to the nitrifying organism, he removed portions of the gelatin film lying between the colonies, thinking that the nitrifying organism must be present there; and on innoculating these portions of the gelatin destitute of colonies into suitable solutions, he actually obtained nitrification. You will remember that, in my second lecture, I referred to this particular method of using gelatin plate cultures for the isolation of organisms which refuse to grow on gelatin.

But these discoveries had not completely explained the phenomenon of nitrification, for the organisms separated in these three independent investigations possessed in each case only the power of converting ammonia into nitrous and not into nitric acid. Nitrous acid is an intermediate body which, curiously, is rarely found, excepting in very minute quantities in soil, nitric acid being comparatively far more plentiful. The changes will be more clearly understood by reference to the chemical equations:—

$$(1)\quad \underset{\text{(Ammonia.)}}{NH_3} + \underset{\text{(Oxygen.)}}{3\,O} = \underset{\text{(Water.)}}{H_2O} + \underset{\text{(Nitrous acid.)}}{HNO_2}$$

$$(2)\quad \underset{\text{(Nitrous acid.)}}{HNO_2} + \underset{\text{(Oxygen.)}}{O} = \underset{\text{(Nitric acid.)}}{HNO_3}$$

The organisms separated by Winogradsky, by Warington, and by myself, possessed only the property of effecting the first of these changes, they were absolutely destitute of the power of bringing about the second.

That this organism is unable to bring about the second of these reactions is particularly remarkable, inasmuch as this is the one which can be most readily accomplished by purely chemical means.

Thus the powerful oxidising agent, potassium permanganate, has no action on ammonia, whilst it readily oxidises nitrous to nitric acid.

[Experiment.—Add potassium permanganate to a solution of ammonium sulphate acidulated with sulphuric acid, the pink colour of the permanganate is not discharged.]

[Experiment.—Add potassium permanganate to a solution of potassium nitrite acidulated with sulphuric acid, the pink colour of the permanganate is at once discharged.]

In fact, in order to bring about the oxidation of the ammonia by chemical means, we have to resort to one of the most powerful of oxidising agents known to chemists, viz., ozone; but this agent, then, produces nitric as well as nitrous acid.

[Experiment.—Show the presence of nitrous and nitric acids in ammonia which has been submitted to the action of a current of ozonised oxygen.]

The power of oxidation possessed by our nitrifying organism is, therefore, altogether unique, doing as it does the arduous work of converting ammonia into nitrous acid, but absolutely refusing to undertake the trivial task of converting nitrous acid into nitric acid.

But how, then, is the nitric acid which is found in the soil produced, seeing that these organisms only yield nitrous acid?

At the time when I found that the organism which I had separated produced nitrous acid exclusively, I pointed out that it was doubtless explicable on one of the two following alternative hypotheses:—(1) The nitrous and nitric acids are produced by totally distinct organisms; or (2) one organism produces nitrous or nitric acid according to the conditions under which it is growing.

More recent researches of Warington and Winogradsky have shown that the first of these two alternative hypotheses is the correct one; for, by making cultivations of soil in a solution containing nitrous acid and no ammonia, a micro-organism has been isolated which is endowed with the capacity of transforming nitrous into nitric acid, but has no power of oxidising ammonia.

FIG. 22.

NITRIC FERMENT (Winogradsky).

This second organism, or nitric ferment, as we may call it, resembles in its activity the purely chemical oxidising agent, potassium permanganate, which, as we have seen, has no action on ammonia, but rapidly converts nitrous into nitric acid.

The process of nitrification in the soil now becomes intelligible in its entirety. It is the work of two independent organisms, the first of which converts ammonia into nitrous acid, whilst the second transforms into nitric acid the nitrous acid produced by the first.

Not only is this process of nitrification going on in all fertile soil, but enormous accumulations of the products of this process, in the shape of nitrate of soda, are found in the rainless districts of Chili and Peru, from where the Chili saltpetre, as it is called, is exported in immense quantities, more especially to fertilise the overtaxed soils of Europe. Thus, during the first six months of 1890 there were brought to the United Kingdom 90,000, and to the European Continent 480,000 tons of nitrate of soda from South America.

FIXATION OF FREE NITROGEN BY PLANTS.

There is yet another agricultural question of tremendous importance, both practically and theoretically, which I must touch upon in my lecture this evening.

For nearly a century past, agricultural chemists and vegetable physiologists have been debating as to whether the free nitrogen of our atmosphere can be assimilated by plants. This question was answered in the negative by Boussingault about 50 years since. The problem was again attacked by Lawes, Gilbert, and Pugh, about thirty years ago, and their answer was in the negative also. In the course, however, of their continuous experiments on crops, Lawes and Gilbert have frequently pointed out that whilst the nitrogen in most crops can be accounted for by the combined nitrogen supplied to the land in the form of manures and in rain-water, yet in particular leguminous crops, such as peas, beans, vetches, and the like, there is an excess of nitrogen found in the crop which cannot be referred to these obvious sources. It has, indeed, been known for 2,000 years that the fertility of the soil can be improved by the growth of leguminous crops.

The question remained in this unsatisfactory state until again revived by M. Berthelot in 1876, whilst subsequently the most conclusive experiments were made by two German investigators, Hellriegel and Wilfarth, who not only showed that this excess of nitrogen in leguminous crops is obtained from the atmosphere, but, what is more interesting to us, that this assimilation of free nitrogen is effected by means of certain micro-organisms flourishing in and around the roots of these plants, for when these same plants are grown in sterile soil the fixation of free atmospheric nitrogen does not take place.

The manner in which these micro-organisms assist these leguminous plants in the accumulation of nitrogen is exceedingly remarkable. When these micro-organisms are present in the soil, they occasion the formation of peculiar swellings or tuberosities on the roots of the leguminous plants, these tuberosities being never formed in sterile soil.

On microscopic examination these tubercles

FIG. 23.

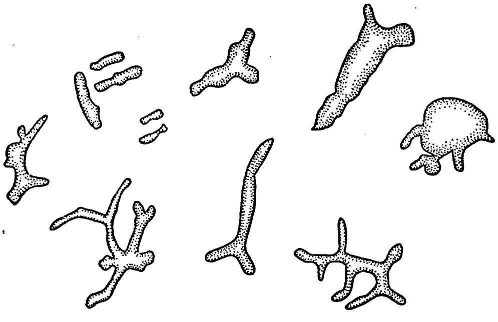
(*b*) Bacteroids present in considerable numbers in each of the polygonal plant ce'ls. The ramifying growth has disappeared.

FIG. 25.

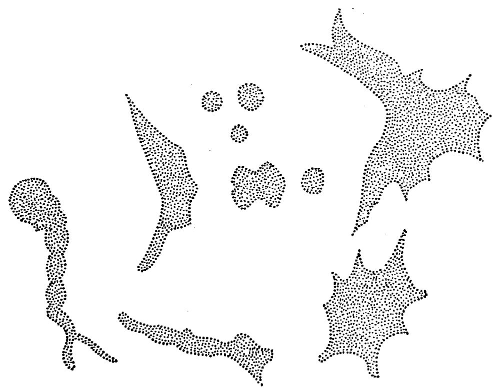


INDIVIDUAL BACTEROIDS, HIGHLY MAGNIFIED. (After Laurent.)

are found to contain amongst their cells a ramifying growth which subsequently gives rise to a number of small cells having much the appearance of bacteria, although the precise group of organisms to which they belong is one of those numerous points on which morphologists cannot agree. As long as this point is still *sub-judice* it is perhaps most convenient to call these small bodies *bacteroids*. In the foregoing figures, which are prepared frcm the beautiful drawings of M. Laurent, the appearance of these ramifying growths and of the bacteroids to which they give rise are represented.

These bacteroids can be cultivated on artificial media like ordinary bacteria, and the next slide shows the appearance of some of the colonies to which they give rise on gelatin plate culture.

FIG. 26.



BACTEROID-COLONIES ON GELATIN-PLATE. (After Laurent.)

The careful investigation of these tubercle-producing organisms has shown that each species of leguminous plant has its particular bacteroid which is more potent in the formation of these tubercles on the given species than the tubercle bacteroids of other leguminous species. In this connection, some very striking and highly instructive experiments have been made by Prof. Nobbe, of Tharand.

This investigator has found that if pure cultivations of the bacteroids from a pea-tubercle are inoculated into the roots of a pea-plant, a more abundant growth and fixation of nitrogen by this pea-plant takes place than if it is inoculated with pure cultures of the bacteroids from the tubercles of a lupin or a robinia; whilst, conversely, the robinia is more beneficially affected by the application of pure cultures from robinia-tubercles than by those from either pea-tubercles or lupin-tubercles.

The exact manner in which the atmospheric nitrogen is rendered available for these leguminous plants possessing root-tubercles is not perfectly understood, but the general impression is that the micro-organisms present in the tubercles take up the nitrogen and elaborate it into a form which can be assimilated by the plant. Whatever the secret of the process may be, it is perfectly certain that the presence and vital activity of the micro-organisms which give rise to the root-tubercles is the indispensable factor.

PEA-PLANTS. (After Nobbe.)

No. 1. Inoculated with pure cultures from tubercles of pea. No. 2. Inoculated with pure cultures from tubercles of lupin. No. 3. Inoculated with pure cultures from tubercles of robinia.

The inoculations were all made on Aug. 14, 1890, and the plants photographed on Oct. 9, 1890.

The great importance of this discovery in vegetable physiology it is unnecessary for me to dwell upon, we have to recognise in these micro-organisms the invaluable agents whereby the atmospheric nitrogen, which is in itself worthless, both to animals and ordinary plants, is actually rendered available directly for the nutrition of plants, and therefore indirectly for the sustenance of animal life on our planet.

I regret that the time has now come for me to bring to a close my discourse on the subject of these microscopic creatures which surround us, and which are in so many cases performing works of inestimable value. I must, in the first place, offer you my sincerest thanks for the kindness and patience with which you

have listened to much which was doubtless not new to many. It has been my endeavour to present to you in outline the principal points which are at present exercising the minds of those who are devoting their lives and energies to the study of fermentation phenomena, using

that term in its widest significance. From what I have said, you will see that the width of that significance is daily becoming greater and is all but coextensive with life itself. As I have pointed out, the fermentation-industries must no longer be supposed only to include brewing, distilling, wine-production, vinegar manufacture, and a few others as heretofore, but the principal fermentation-industry, which is far more extensive than all the others put together, is agriculture itself.

The study of these fermentation phenomena is progressing with such rapid strides, and the accumulated material is already so overwhelming, that I have of necessity had to omit much that might have well found a place had time only permitted. If, however, in marshalling before you, as I have done, the recent discoveries in this branch of science, I shall have succeeded in arousing in any one here present such interest as will lead to his entering the ranks of the cultivators of this fertile domain of science in which so much still awaits the explorer's hand, then, indeed, my efforts will have been amply rewarded, the object and purpose of this course of lectures will have been realised and fulfilled.

Miscellaneous.

THE TEXTILE INDUSTRIES OF TREBIZOND.

In the textile industries of Trebizond, which, according to the French Consul there, are not in a very flourishing condition, the following articles are manufactured:—*Manoussa*, *Kétau*, *tchumbels*, and *havli*, all of which are composed of linen or cotton, and a variety of silk tissues. *Manoussa* is a species of cotton cloth, striped and party-coloured, strong and well dyed, of which the natives use considerable quantities, either for clothing or upholstering. It is estimated that, at Trebizond, there are 600 looms manufacturing this article, a piece of which, measuring from 6 to 8 metres long and about 50 centimetres wide, is valued at from 7 to 13 piastres. On an average, 40,000 pieces of the cloth are sold annually, either for local consumption or for the towns on the coast and the neighbouring villages, and the yarns used in its manufacture come from England and Germany. *Kétau* is a tissue of hempen yarn manufactured principally at Kizeh and its environs, and generally known as Trebizond cloth. The annual production is about 150,000 pieces, and each piece is 27 metres long and about 50 centimetres wide, being valued at from 14 to 250 piastres, according to the degree of its fineness. This cloth, although somewhat resembling muslin, offers considerably more resistance, and is used in making shirts and drawers. Large quantities are exported to warm climates, such as Bagdad, Bassorah, Yemen, and Hedfaz. It is in the environs of Kizeh and in the plain of Tcharchamba, that the raw material—that is, the hemp—used in the manufacture of this cloth is found. On leaving the loom it is perfectly black, and is bleached by sea water. The finer descriptions of cloth are ornamented at one of the extremities by designs in fine gold, and the common qualities by designs in imitation gold. By *tchumbels* is understood a sort of muslin handkerchief, manufactured with pieces of stuff imported from England, these being dyed at Trebizond, and ornamented in the centre and at the four corners with hand-made designs of various flowers. The native women use them as head coverings, and preserve this coiffure during the night as well as during the day. The annual production is valued at 200,000 handkerchiefs, and the price varies between one and three piastres each. *Havli* is a cotton tissue used for making towels and bath wrappers. This article is manufactured in larger or smaller pieces, of which the price varies from 6 to 10 piastres for towels, and from 20 to 25 piastres for bath wrappers. This description of tissue has been imitatated by French manufacturers, and is sold in French houses as Turkish serviettes, &c. The tissues of silk manufactured in the country are composed of three principal kinds, the *tcharchaf*, a species of veil, with which the women cover themselves when out of doors; the *puchtemas*, a species of apron of light tissue, with large stripes of various colours; and, finally, the *kéfié*, or girdles of striped stuff, parti-coloured and fringed. The *tcharchaf* are of three kinds, white, with a broad band of violet; striped, with grey on a white ground, in the form of checks; and quite plain, and dyed in red, violet, or black. The two first descriptions are worn by Christian women, and the third by Mussulman women. The white *tcharchafs* are held in the highest esteem, and fetch prices varying from 300 to 350 piastres each; those with checks, from 200 to 250 piastres; and the plain description or those dyed in red, violet, or black, realise from 220 to 240 piastres. The *puchtemas*, as well as the *kéfié*, are sold at the rate of 40 to 50 piastres each. The raw silk which is used in making up these stuffs comes from Amassia, Bafra, and Tcharchamba. The average production of Amassia raw silk is estimated at 10,000 ocques annually (ocque = 2·8 lbs. avoirdupois), and its price is from 46 to 54 francs the ocque. It is estimated that from 12 to 15 ocques of cocoons yield one ocque of silk. The Tcharchamba and Bafra yield of raw silk is from 300 to 400 ocques annually, and the whole of this quantity is used at Trebizond.

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

Chicago Exhibition, 1893.

REPORT ON THE PROGRESS OF WORK.

By Colonel Hayes Sadler.

[*Continued from p.* 947.]

ALLOTMENTS AND EXHIBITS.

No detailed statement of the allotments which have been made can be given, but applications have been received for more than five times the amount of space at the disposal of the Directors, who are engaged in making arrangements to provide room for only the most desirable exhibits. The allotments to foreign Governments have all been completed, except those to Italy, Switzerland, and the Netherlands, which countries have recently appointed official Commissions, and endeavours are being made to satisfy their demands. All the space has been allotted in the Manufactures and Liberal Arts Building, and, no further space being available, the Direction have recently given to Spain a small portion reserved for United States exhibits, with a view to accommodate that country, to which no space had been allotted. Among the allotments in the Fine Arts Building, 24,324 square feet hanging space have been reserved for America, 21,325 square feet allotted to England, 2,895 square feet to Canada, 29,201 square feet to France, and 20,340 square feet to Germany. A special piece of ground has been granted to the Krupp Gun Company, for the erection, at their expense, of a building to contain the 120-ton gun—the largest ever built—and other ordnance.

The enormous demand for space—so many times greater than these gigantic buildings can accommodate—demonstrates the enthusiasm reported to exist, not only in America, but in almost every foreign country, with regard to the Exhibition; and preparations on a large scale seem everywhere to be progressing, so that each country may be as well or better represented than on any former occasion.

To enumerate the nature and variety of foreign exhibits promised would be impossible, but there are indications, in many instances, of a desire to outstrip former efforts, as well as other countries, in the character and completeness of display; and it has been found impossible to meet additional demands for space which have been made since the importance of the Exhibition has been recognised. There are some foreign countries, especially the Central and South American Republics, which have never been represented in the manner they will be at the Chicago Exhibition.

Foreign exhibitors are permitted to fix upon placards attached to their exhibits the price at which these will be sold at the place of manufacture, or in and out of bond, exclusive or inclusive of the Customs duties of the United States. All exhibits will be admitted free of duty, but must pay duty if they are sold or remain in the country. Such articles also as may be imported solely for exhibition which may be consumed or destroyed in their application to the process they are intended to illustrate, will be admitted free, and satisfactory evidence of such consumption or destruction will be accepted at the close of the Exhibition as authority for closing the Customs accounts of the respective articles. No citizen of any other country will be held liable for the infringement of any patent granted by the United States, or of any trade mark or label registered in the United States, where the act complained of shall be performed in connection with the exhibit of any article or thing at the World's Columbian Exposition.

The Collector of Customs has already taken possession of the bonded warehouses, which are finished, and such exhibits as have come to hand are now deposited there, while all fresh arrivals will be delivered on the grounds. The terminal charges on exhibits sent to the World's Fair are reduced from 4d. to 3d. per 100 lbs., which must be paid both ways.

With regard to American exhibits and inventions there will be a great deal to see. This continent has been but imperfectly represented at European exhibitions, and yet nowhere have greater advances been made in all branches of manufacture and trade, in labour-saving machinery and appliances, in science and invention. The show of machinery, minerals, manufactures, transportation, and agricultural produce promises to be very extensive and

complete. Exhibits from some of the States have already arrived, and selection has been found necessary, from want of space, to meet all demands. In the Transportation Building will be concentrated every description of means of locomotion by land or water, locomotives, fully equipped trains, marine appliances, equipments, naval armaments, and models of ships from leading builders and companies, besides models of lighthouses, bridge and harbour works, lifeboats, steam and electric launches, bicycles, &c. The Forestry Building is surrounded by a colonnade composed of timber from all the States of the Union. The pillars are in groups of three, the centre one, of 20 inches diameter, flanked on each side by a column of 12 inches in diameter, and all the hard woods of the country are represented. The Women's Building promises an interest peculiar to this Exhibition, and will contain all the finest efforts of the industry and talent of the sex. The line of separation, however, to be drawn between the women's works to be exhibited in this building and those to be exhibited with men's work in the different exhibition buildings, appears less clear. The project of providing a Children's Home associated with this building, for the purpose of relieving tired mothers, is fairly launched, and a building will be erected by subscription, to be furnished with play-rooms, children's books, and scientific toys, under the superintendence of kindergarten teachers. A Women's Dormitory Association has also been formed, with a view to provide women who visit the Fair with proper accommodation at reasonable rates. The Horticultural Show promises to be not only bewildering in extent, but the most complete ever made or attempted, and will form an important feature of the Exhibition in a scientific point of view, as well as in the adornment of the grounds. The building, which is finished, and has been in use for some months, is 998 feet long by 250 feet wide, and the display will include fruit and all that pertains to horticulture. In the southern portion will be the viticultural exhibits, in the rear curtains the exhibits of fruit from all parts of the world, and where it is not possible to show the natural fruit, even with the means of refrigerators and cold storage, perfect wax models will be displayed. The floricultural exhibits will be distributed, and, so as to allow for recovery from the check of transplanting, 50,000 plants and shrubs are already growing in the grounds. In the front curtains will be hothouse and greenhouse plants, and among these a magnificent show of orchids, of which, it is said, there will be 2,000 different varieties. There will be every description of tropical vegetation, with orange groves and other trees in full bearing, and the plan of growing trees by electric light and with the aid of electric currents will be exemplified. There will also be collections of insects, beneficial or injurious to the fruits of horticulture. In long lines of greenhouses to the rear of the building plants will be brought to perfection or stowed away. Six acres in front of the main building, besides spaces round many other constructions, will be devoted to floricultural exhibits; the wooded island, which covers 15 acres, is being laid out with beds of shrubs and flowers, divided by winding walks; at the north end of the island will be a Japanese temple surrounded by choice plants from that country. The amount of space asked for here by the States, particularly California, and by foreign countries, has been far beyond the power of allotment, and some displays will be extended to the Midway Plaisance.

As the enterprise develops, the more convincing it appears that the Chicago Exhibition of 1893 will be by far the most extensive and important which has yet taken place. The effect on the avenues of trade will probably be wide and far spreading. Considerable changes and diversions may result, new connections will be made, and old ones lost. Commerce does not stand still nowadays, nor is trade in these times of great competition won or retained without continued exertion; and however greatly this Exhibition may benefit manufacturing and commercial enterprises in the United States, it undeniably offers the best possible opportunity for advertising, by means of exhibits, to the manufacturers of other countries. The yield out West is large, and there European goods are not widely seen or known, and, at all events, only obtainable at the prices fixed by the American importer, and the liberty, therefore, conceded of affixing on exhibits their cost in and out of bond will be of great advantage in attracting customers; the fear that methods may be copied seems scarcely to warrant abstention or weigh against the advantage of such advertisement, for there are few inventions unknown here or otherwise unobtainable. Rapid changes are taking place in this country, and manufacture is constantly tending to migrate where circumstances are the most favourable and material nearest at hand; formerly the East supplied

the West; the East is now greatly furnished with manufactures of wood and iron, furniture and other trade goods from the factories of Chicago and district; agencies in the East now exist for the shipment and export of many goods manufactured in the West, where but a very few years ago the agency was in the West for the Eastern manufacturing firm. This is a migratory age; communications and transit become yearly more rapid, economic changes more frequent, and the influence of advertisement more extended.

The Exhibition will probably be visited less, proportionately, by pleasure seekers than were former exhibitions, and more by persons interested in the various exhibits. Foreign visitors will be almost entirely those who come with the special view of profiting by and interesting themselves in the goods exhibited, while as regards the United States there are practically no pleasure seekers here, all men being workers and personally and actively engaged in the different businesses of life. Of these vast numbers will come from all parts of the country, bent on taking advantage of every new channel of trade, eager to obtain the best return for capital, and in search of the most perfect methods of diminishing the cost of product and encouraging labour. The whole nation is occupied in business, and the result has been the accumulation of immense wealth, which is less hampered by consequent expenses here than elsewhere. This available wealth is yearly increasing, and so is the disposition to purchase articles of value, the artistic productions and finer works of older countries, and collections or specimens of historic pre-eminence. A love of the beautiful and an appreciation of art is fast growing up, and while the keen business of amassing riches is never lost sight of, the desire to fill their public institutions and private residences with works of art and the product of genius shows a marked advance. Thus, to the foreign exhibitor greater advantage is probably offered by exhibiting at Chicago, where enterprise and wealth have made such strides, and which city is not only the rising business centre, as it is now the centre of the population, of the United States, than could perhaps be offered an exhibition in any other locality.

Other Works and Arrangements.

Besides the principal constructions mentioned above, there are many other buildings and works within the park which will, it is said, be all completed by the time fixed for the dedication. A water station is established for supplying the grounds and buildings and for fire purposes, and the most approved drainage system has been established; about nine-tenths of the water and drainage pipes are laid. An electric lighting establishment has been completed, and about two-thirds of the work done for the incandescent lights. The contract for the installation of 92,000 lamps was taken at £79,800, and arc lights have been contracted for at £21,000, the subways, rubber-covering, and power costing an additional £14,575. The Music Hall, Casino, and Peristyle, which will cost £57,311, are well in hand, and the big pier contracted for will be finished by October 15. The columns and trusses of the Casino are in place, and the columns of the Peristyle as far as the opening connecting the outer harbour and the basin. The foundation piles for the statue of America, to be placed in the lagoon opposite the Administration Building, are driven, and the framework for the big statue of the Republic has been started. All the grading and planting in the grounds have been finished, and a large force of men is engaged in laying the walks and building the roads, which are not yet finished. Dredging the lagoons and harbour, at a cost of £21,900, is nearly finished. The statue of Columbus is well in hand, at a cost of £8,000, and the grand fountain, contracted for at a price of £11,200, will be immediately commenced. The permanent bridges and the railing of the waterways are complete, and all other works are well in hand.

The movable platform has been condemned, and an intramural elevated railway, with stations every 1,000 yards, will be constructed for the purpose of conveying visitors from one part to another of the extensive grounds covered by the various buildings. The cars will be moved by electric traction on the trolley system, with the wires between the rails. It is said the capacity will be 20,000 persons per hour; and passengers will be able to alight at any part of the grounds. Steam and electric launches have been tested, which will ply on the waters of the park between different landing places; express boats will take visitors round the waters, and omnibus, or cab-boats, can be engaged to go from one part to another.

An appropriation of £35,000 has been made for an orchestra of 120 performers during the time the Exhibition is open. Arrangements are being made for a variety of other choral, orchestral, and international musical enter-

tainments; and there will be a Recital Hall, Music Hall, and Festival Hall for 2,000 singers and an audience of 7,000. There will be postal, telegraphic, telephonic, express, and other facilities on the spot. Physicians will be attached to the medical bureau of the Exhibition, where persons falling sick or requiring medicines will be attended, but no drug stores will be allowed. About 150 restaurants will be situated in the principal buildings and in the grounds; in the Manufactures and Liberal Arts Building there will be 16 large *cafés* and 72 private dining rooms, lunch counters in the Transportation Building, and fish lunches in the Fisheries Building. Liquor will be allowed to be sold, but no bars or saloons will be permitted.

The World's Auxiliary Congress, promises to form a very important feature of the Exhibition, and foreign governments have been invited to participate and render co-operation. The work has been organised in 16 departments, and more than 100 general divisions, in which congresses will be held. The most undoubted authorities on every branch of science and art, and representatives of leading institutions from all parts of the world, have been invited, and are expected to attend.

With the 13 immense principal constructions, at least 100 special Exhibition structures, and other works, Jackson-park will have the appearance of a city in itself. Outside the park, along the Midway Plaisance, will be grouped a number of other structures, for which concessions are required.

[*To be continued.*]

Proceedings of the Society.

CANTOR LECTURES.

USES OF PETROLEUM IN PRIME MOVERS.

By Professor W. Robinson, M.E.,
Assoc. M.Inst. C.E., University College, Nottingham.

Lecture I.—Delivered February 29, 1892.

Introductory.

The use of petroleum and its products in various forms, for heating and motive power purposes, has received much attention during the last few years. Especially recent important advances have been made in the application of oil as fuel, instead of coal gas, in the cylinder of the internal combustion engine since last year, when I had the honour to bring the subject before this Society. But with this extended use of mineral oil, both as fuel and lubricant, experience goes to show that the general public, and even some practical engineers, have rather vague notions, and exhibit wonderful ignorance, as to the character and properties of petroleum.

What is meant by Petroleum?

Perhaps such ignorance is in part due to the fact that the one word *petroleum* is often used to describe very different substances, which are, in themselves, of complex composition and constitution. Thus in the widest sense of the term, *petroleum*, or *rock-oil*, comprises not only the different mineral oils which flow from the earth's crust, but also the solid as well as partly gaseous hydro-carbon products obtained by the distillation of bituminous shales, Boghead coal, and peat. There are then, at least, two distinct classes of mineral burning oils. The one extracted from bituminous shale is sometimes called "paraffin oil," and the other, known as "refined petroleum," is the product of crude petroleum found in the earth in the liquid state.

Different Sources of Supply.

Immense stores of natural crude petroleum exist in America, and in Russia especially about the Caspian Sea, and the supply from these sources appears to be unlimited. Oil is to be met with in other countries, as Peru, India, Burmah, Galicia, and probably in England.

Bituminous shales are also found in great abundance in many parts of the earth's crust. In Great Britain the manufacture of the various commercial products from shale has grown up into an important chemical industry. In 1850, Dr. James Young pointed out the way to produce paraffin oil by distillation from shale. Shortly afterwards the Americans started coal-oil refineries, and the American refiners imported Boghead mineral from Scotland, and were even using their own bituminous and cannel coals to make oil in the year 1859, when the great discovery was made that any quantity of crude petroleum oil was to be had by simply sinking wells for it, and since then the petroleum industry has grown rapidly.

Kinds of Oil Available.

Crude shale-oil, got by the destructive distillation of bituminous shale in closed retorts, is a dark green, strongly smelling, viscous fluid

of specific gravity ·865 to ·870, and resembles crude natural petroleum obtained direct from oil-wells in the earth.

I have here on the table some bituminous shale itself, and you will observe that the samples of crude oils from the oil wells in the United States, and that from the wells at Baku in Russia, although varying slightly in colour and appearance, are much like the heavy shale oil.

Now these three crude oils—the product of bituminous shale, and crude petroleum oils from America and Russia—are subjected to somewhat similar processes of treatment, being first split up by *fractional distillation* into several hydro-carbon products, which are separated and then refined by slightly different processes of *chemical purification*, yielding the various finished commercial products, and known as refined petroleum.

This part of our subject was fully dealt with in a course of Cantor Lectures on "Petroleum and its Products," delivered in this room by Mr. Boverton Redwood, in 1886, after he had visited the principal oil-fields and studied the subject thoroughly; and, through his kind ness, I have a few samples of the chief petroleum products here on the table before you to-night.

Supply of Petroleum.

The production of these oils is steadily increasing, and new oil-fields are being developed. In 1889, the total production of crude petroleum in the United States was 35,000,000 barrels (each of 42 American gallons); and, during the year 1890, the shipments of crude petroleum from the oil regions of Pennsylvania and New York alone amounted to 30,628,739 barrels (of 42 American gallons). In these fields 6,358 new wells were completed during the year 1890, the number for 1889 having been 5,489. The average daily production was thus increased from 61,306, in 1889, to 78,588 barrels in 1890.* In Russia, the Baku oil-fields produced 68,000 barrels (of 42 gallons) per day during 1889, and this was increased to 80,000 barrels per day in 1890. In 1890, the shipments of petroleum oil from the United States and Russia to the United Kingdom was 2,144,651 barrels, of which 1,357,122 barrels were American.

Properties of Oils.

Crude petroleum consists of a mixture of hydrocarbons which have very different boiling points. The lighter constituents are very volatile, some of them evaporating rapidly when the mixture is exposed to the air. Thus, a little petroleum spirit poured on the hand or table evaporates, and should leave no odour. If heated in a crucible over boiling water, a good sample of petroleum spirit evaporates rapidly, and leaves no black oily residue of heavy hydrocarbons behind. The light oils, or highly volatile hydrocarbons, as gasoline, petroleum spirit, and benzoline, are dangerous, because they readily exist in the gaseous state, and are exceedingly inflammable.

Products of Distillation.

When the heavy crude oil is heated in a still, the constituents, having different boiling points, are distilled off as the temperature is gradually raised. The weight and boiling points of the products of distillation are found to increase gradually in much the same proportion. After the light oils we get separated off the "burning oils" of commerce, known as "kerosene." In the next distillation, in which superheated steam is used, the product is the oil used for lubricating machinery; but between the "burning oils" and "lubricating oils" we have the so-called "intermediate" oils. The heavier products obtained after this are "solid paraffin wax" from shale, and "vaseline" from petroleum. Then there is a residue left in the form of a heavy liquid, which is used as fuel, known as "residuum" in America, and "astatki" in Russia.

The crude American petroleum consists chiefly of a mixture of hydro-carbons, known to chemists as paraffins ($C_n H_{2n+2}$), of which marsh gas (CH_4) is the first member. These paraffins, when heated above their normal boiling points, are split up, and become changed or decomposed into olefines ($C_n H_{2n}$) as $C_2 H_4$, at the same time gas is evolved and carbon deposited.

Cracking Process.

We find, then, from the heating of paraffins or petroleum above their normal boiling points, as will occur when some distillate is condensed in the still, and falls back into the hot liquid, which is at a higher temperature than the boiling point of the condensed distillate, the latter becomes decomposed, and the resulting products mainly consist of a mixture of various paraffins and olefines. Heavy condensed oils of specific gravity ·880 may thus be split up or decomposed, by properly regulating the heat,

* See "The Year-Book of Commerce" for 1892, and the "Statesman's Year-Book." The former gives a review of the petroleum industry.

into lighter oils of gravity ·820. This process of breaking up heavy oils into lighter burning oils is called "cracking," and is one of the means by which Americans obtain a much larger yield of burning oils than the petroleum would produce by ordinary fractional distillation. One peculiarity of burning oils manufactured from American petroleum by the "cracking" process is, that they contain a large proportion of olefines depending upon the particular method and conditions of preparation; whereas, the paraffins are characteristic of crude American petroleum.

The lubricating oils are mainly made up of olefines, and are purified by filtration through animal charcoal.

Tests of Petroleum.

You will observe that these different refined petroleum oils vary in colour from clear or colourless burning oils—"water-white"—to pale yellow, straw colour, amber, and dark brown lubricating oils.

We distinguish these oils in a rough and ready way by their colour, peculiar blue fluorescence, and smell; but the properties of oils are better ascertained by putting test questions in the form of experiments, though it must be borne in mind that in the interpretation of the replies, strict accuracy and careful attention to details are of the greatest importance.

Specific Gravity.

Now, the first question which arises is—What is the weight of the oil?

The specific gravity of an oil is the ratio of its weight to that of the same bulk of distilled water at the temperature of 60° Fahr. The standard substance, water, is taken as 1 or 1,000. The specific gravity of oil is usually determined by means of an ordinary direct reading hydrometer. A suitable hydrometer, such as the instrument in my hand, is immersed in the oil, and if it floats freely, you read off the scale number at the surface of the oil that corresponds to the specific gravity. It is important that the temperature of the instrument should be the same as that of the oil, and both the oil and instrument should have remained in a bath for some time, to have reached the standard temperature of 60° Fahr. or 15·5° C., in order that the reading may be of use for reference with other oils under the same conditions. There must, therefore, be a standard temperature for reference; and sometimes the oil takes a considerable interval of time to arrive at the exact temperature of the bath. You see that the weight of the floating instrument is equal to the weight of the liquid oil displaced by it. Here the weight of the float remains always the same, and it is simply equal to the weight of the liquid displaced; therefore, this instrument will sink further into light warm oil than in cold heavy oil, so that the bulk immersed varies inversely with the gravity of the liquid. The temperature should be carefully noted in all cases.

Use of Derham's Hydrometer.

Accurate determinations may be made by means of another instrument I have here, known as "Derham's hydrometer." It is an improved form of the Sikes hydrometer, and enables you to determine the specific gravity of liquids from ·780 to 1·000 directly from the scale reading, without reference to tables, by the use of poises, which consist of little platinum weights fixed in pieces of ebonite, the weight and bulk of each poise being correctly adjusted beforehand to the middle value of the range of specific gravities it is intended to measure. Below the usual gilt ball there is the little stirrup, into which are fixed these poises of different sizes. It is necessary that the law connecting together the bulk of the instrument immersed, and the specific gravity of the oil should be exactly fulfilled. The scale reading goes from 0, at the top, to 20 at the bulb. Starting without any poise at all, when the instrument floats to the zero mark on scale, the specific gravity of the liquid is ·780. When another heavier liquid is tried, it buoys up the instrument more, and, consequently, the scale reading increases until you reach 20, and this, added to 780, gives the specific gravity 800 or ·800. For heavier liquids the poise marked 800, is placed in the stirrup, and the scale reading added to this number gives the gravity. In this way, by selecting the proper one out of a graduated series of poises, the weights and bulk of which have been accurately adjusted, the specific gravity of different kinds of oil may be quickly and accurately ascertained, and the one instrument takes the place of a whole series of hydrometers.

Mohr's Balance.

Mohr's specific gravity balance enables us to determine rapidly with accuracy the specific gravity of gases and liquids within a very wide range. The simplest form of this little instru-

ment is on the table, and I wish to show you how to work with it. It is simply a balance. The float hangs from the arm of the balance by a thin piece of platinum wire. The float is balanced first of all in air, and when immersed in the oil it is buoyed up, and loses weight equal to that of the oil displaced. Then put one of a graduated series of little weights or riders along the graduated arm until balance is restored. The marked positions of the riders give the specific gravity. Thus the heaviest rider represents gravities from ·1 up to ·9, depending on its position along the arm to give balance. This heaviest weight, being at the extreme end, would make the balance true, if the float were immersed in distilled water at the standard temperature, that is the standard specific gravity 1 or 1,000. Smaller riders are used in the same way for the second and third place of decimals. This float also acts as a simple thermometer. Instead of it plummets of glass may be used for very heavy liquids. The float may be kept constantly in the liquid, and the temperature carefully noted when there is balance. This is a simple and very accurate method of observing the specific gravity of the oil at different temperatures.

Besides, the *specific gravity bottle* may be used to find the gravity of oils in the laboratory, where a delicate balance of great sensibility is available.

Expansion due to Increase in Temperature.

You will have noted that, in order to ascertain the specific gravity accurately, it is always necessary to observe the temperature of the oil, so that the temperature correction may be made to reduce the weight of unit volume to what it would be under standard conditions. Oils change very considerably in volume with change of temperature. I have measured the expansion of several samples of ordinary burning oils by the *weight thermometer*, and checked the results by comparing the specific gravities by Derham's hydrometer at 15·5° and 40° C., the average co-efficient of expansion for this range of temperature is about ·00084 per degree Centigrade for American Royal Daylight oil of specific gravity ·811, and ·00085 for Russian ordinary burning oil (Russoline) of specific gravity ·824, whilst Russian "Lustre" oil of gravity ·825, and the Broxburn Lighthouse oil of gravity ·810 have the same co-efficient of expansion ·00089 per 1° C. It clearly follows, since these oils increase so rapidly in volume with increase of temperature from winter to summer in this country, that temperature corrections must be made in finding their specific gravity. We have, then, the simple rule, *to find the correct specific gravity we must add to or substract from the observed specific gravity* ·0007 *for every* 1° *C. above or below the standard temperature* 15·5° *C., or* ·0004 *for every* 1° *Fahr. above or below* 60° *Fahr.* This seems to be a fair average of the corrections I have found for several ordinary kerosene oils I have examined, as shown in Table I. (p. 964). In making these determinations, perhaps the simplest plan is to observe the specific gravity of the oil first at the standard temperature, and again at a very much higher temperature, then note the difference in the specific gravity for the given range of temperature, and hence deduce the average change per degree.

Danger of Petroleum Spirit.

Many people do not seem to know the difference or distinguish between ordinary burning petroleum oils called kerosene, which are safe, and a light dangerous petroleum oil such as benzoline, the storage of which in large quantities in town is prohibited by law.

Perhaps the following simple experiment may prove useful on this point to illustrate the danger of the lighter oils, and show you the comparative safety of the burning lamp oils. Here are a number of small tin vessels on a tray, and into each of these I pour a sample of common burning oils—Lighthouse oil, American Royal Daylight, ordinary Russian oil (Russoline). These oils are exposed freely to the atmosphere, and if I apply a lighted taper to the oils, it not only fails to ignite them, but is at once extinguished when immersed in the oils. You see that these oils do not burn, and are not so very dangerous as is sometimes imagined. A lighted match dropped into any of these oils is also extinguished, and even the burning taper with large flame is put out when held in the most volatile of them. Indeed, the electric arc may be made to pass between two carbon rods immersed in the oils without igniting them, but the oils soon become charred by the passage of the spark. A small piece of red-hot iron is made quite cool when thrown into a considerable quantity of any of these oils, although the frequent repetition of this experiment on a sample of oil is not attended with agreeable odours.

TABLE I.—TYPICAL SAMPLES OF PETROLEUM OIL.

On the other hand, if I take the light, volatile, and dangerous oil called benzoline, which is not readily procured in town, except in small quantities from chemists, you see it does not extinguish the lighted taper. On the contrary, inflammable vapour is given off from this oil at the temperature of the room, and the vapour ignites coming in contact with the lighted taper held near the oil, when the flame is a few inches above the surface of the oil, and before it actually touches the liquid. It is obvious that the vapour that arises from this light dangerous liquid is highly inflammable, and explodes often when least expected, causing serious damage and mischief. This is certainly not a safe oil for ordinary use; it is petroleum spirit, or, perhaps, more correctly speaking, an inflammable liquid.

FIRE TEST.—BURNING POINT.

The ordinary burning oils do not give off a large amount of vapour at the atmospheric temperature, even in summer. However, if the temperature of, say, "American Royal Daylight, be raised sufficiently by holding the lighted taper close to the surface of the oil, after some time enough vapour will be given off to ignite and produce a blue flash. This temperature, accurately determined as we shall see presently, is called the flashing point of the oil. If we heat the oil still further, we reach the *burning point*, or *ignition point*, at which the liquid mass of oil is actually ignited and burns steadily. This rough and ready way of gradually heating a little oil in a tea-cup about three-quarters full of oil, placed on warm water in a vessel, was one of the earliest methods of testing the inflammability of oils.

FLASHING POINT.

A thermometer, just immersed in the oil, is held in one hand, and a lighted taper in the other; and it is found that *the temperature*, at which the oil vapour comes off fast enough to give a *blue flash* depends on, first, the time taken in heating the oil; second, the exposure of the oil cup to air draughts blowing on the surface of the oil; third, the size and nature of the test flame, and the distance it is held from the surface; and, fourth, the duration and frequency of the application of the flame. There is, perhaps, no more important test of oil, as regards safety in transport and use, than this one for finding the *flashing point*. This flashing point test is associated with the name of our chairman, who has done us the honour to pre-

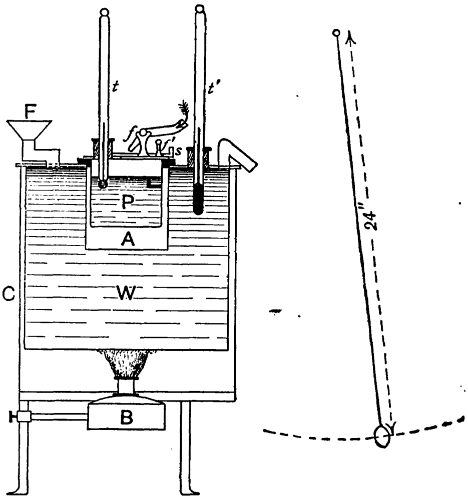
side to-night; and I am of opinion there is no other one man who has done so much as Sir Frederick Abel to insure the safety of the public when using petroleum oil. The "flashing point" of an oil is defined as the temperature at which the oil begins to give off any sensible quantity of inflammable vapour, when enclosed in a certain specified way, so that the vapour burns with a blue flash when a small flame is brought into contact with it. Clearly, the lower the flashing point—that is, the lower the temperature at which the oil gives off a notable quantity of inflammable vapour—the more dangerous the oil is in transport, storage, and use.

We have already seen that petroleum is a complex mixture of hydro-carbons having various boiling points, so that a sample of refined petroleum is usually made up of a graduated series, from comparatively light oil up to heavy oil. Now, we must draw the line somewhere between the petroleum spirit, which is dangerous, and the oil, which is safe; and both experience and legislation founded thereon have arrived at the conclusion that 100° Fahr. for the open test, or, more recently, 73° Fahr. for the close test, is the standard flashing-point, above which an oil may be considered safe, but below which an oil is undoubtedly dangerous in this country. Even a very small per-centage of light oil mixed with a heavier oil gives off vapour rapidly, and can be readily detected by its effect on the flashing-point. Thus, an oil flashing at 113° Fahr., by the open test, is found to flash at 103° F. when mixed with 1 per cent. of naphtha, and at 59° F. with 10 per cent. of the light oil, making the mixture a dangerous inflammable liquid. Indeed, the same oil, mixed with 20 per cent. of naphtha, ignites and burns at 50° Fahr. far below the temperature of this room.

Abel Test.

We have here on the table a standard instrument—the Abel test apparatus—which enables us to give an exact answer to the question, at what temperature is there a sensible quantity of inflammable vapour given off any sample of oil? The Abel close test apparatus and the method of using it are fully described in the Schedule I. of the 1879 Petroleum Amendment Act. The diagram Fig. 1 shows the Abel Tester partly in section. The outside copper vessel, C, contains the water bath, W, which consists of two copper cylinders. The bath, W, is filled by pouring water into the funnel, F, until it begins to overflow at the spout. This bath is heated by the spirit lamp, B. The oil-cup, P, is made of gun-metal or brass tinned inside, and rests upon an ebonite ring, over the air-chamber, A, and has a tight-fitting lid, on which is fixed the gas burner, the flame, *f*, being made 0·15 inch in diameter, the same size as the white bead, *f'*, on the cover. There are in the lid three holes, which can be opened by pulling out the brass slide *s*, and this motion of the slide, by means of a lever, tilts the burner so as to bring the flame, *f*, through one hole in the lid just below it to the space above the oil. The thermometer, *t*, in the lid has a round bulb, just immersed in the oil, and the scale with special points marked on the ivory back. The other thermometer, *t'*, with long bulb indicates the temperature of the bath.

Fig. 1.



Abel Tester.

When applying the test, the apparatus is placed in a position not exposed to currents of air or draughts. The temperature of the water bath at the start of the test is to be exactly 130° Fahr., or 54·5° C. The oil to be tested, if above 65° Fahr., should be cooled down to 60° Fahr., and then poured into the oil-cup, P, carefully, to avoid splashing against the side, until the oil reaches the point of the little bent wire gauge inside the cup. The lid is then put on, and the cup placed in the bath, and the rise of temperature watched on the thermometer in the petroleum cup. When the temperature of the oil is about 66° Fahr. or 19° C., start testing by drawing the slide slowly open while the pendulum,

24 inches in length, makes three oscillations and close it rapidly during the fourth oscillation. In this way the test-flame is gradually tilted through a hole in the lid to the space above the oil. Repeat this operation once for every 1° Fahr. in temperature, until the vapour of the oil gives a pale blue flicker or flash, and then the temperature of the oil is noted as the flashing point. The flashing point of a sample of oil may be defined as the temperature at which the oil begins to give off an appreciable quantity of inflammable vapour when slowly heated in a closed vessel. In this country the lowest flashing point allowed for petroleum is 73° Fahr., or 22·8° C.

The results obtained by the Abel tester are satisfactory, except that slight errors come in the personal equation, from variation in the rate of moving the test-slide. In order to obviate this source of error, in the German modification, a clockwork mechanism is used, which is wound up and the trigger pressed, to move the test-slide automatically. In hot countries, the more volatile hydrocarbons come off readily by the slightest shaking of the oil, consequently it is found better to start applying the test-flame at 56° Fahr., and thus remove small quantities of vapour by the air-currents. Another difficulty is that the cover of the oil-cup gets heated by the test-flame.

For low flashing oils the air-chamber, A, around the oil-cup is filled with cold water to a depth of 1·5 inch, and the water bath, W, is filled with cold water. In testing heavy oils of high flashing point, start with water heated to 120° Fahr., and keep the spirit lamp, B, constantly under the bath.

Any variation in the atmospheric pressure from day to day slightly changes the flashing point of an oil. Experiment shows that the flashing point varies at the rate of about 2° Fahr. for every 1 inch of mercury in the barometer.

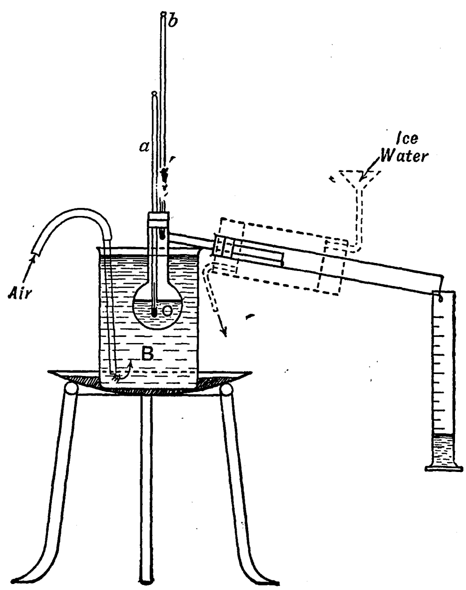
An attempt was made by Salleron and Urbain to deduce the flashing point from the vapour pressure, but this pressure was found to be different with different samples of petroleum having the same flashing point, perhaps because the samples were made up of different mixtures of hydro-carbons.

The flashing-point test enables us to ascertain whether there are very volatile and inflammable hydro-carbons present in a sample of oil. Consequently it is a very good and necessary test as to the safety of petroleum oil for storage and use. Still we cannot by this method determine the exact proportion of the more volatile hydrocarbons present, much less obtain further information as to the nature of the oils.

Fractional Distillation.

We are led, therefore, to try to find by *fractional distillation* the composition of the different petroleum oils, as regards the proportion of their more volatile constituents. In order to obtain comparable results it is necessary to use the same apparatus and work under the same conditions throughout. The same measured volume of oil taken in every case, equal to that of 1,000 grains of pure water at 60° Fahr., was heated in a glass flask, O, Fig. 2, by the steady flame of a

Fig.



Fractional Distillation Apparatus.

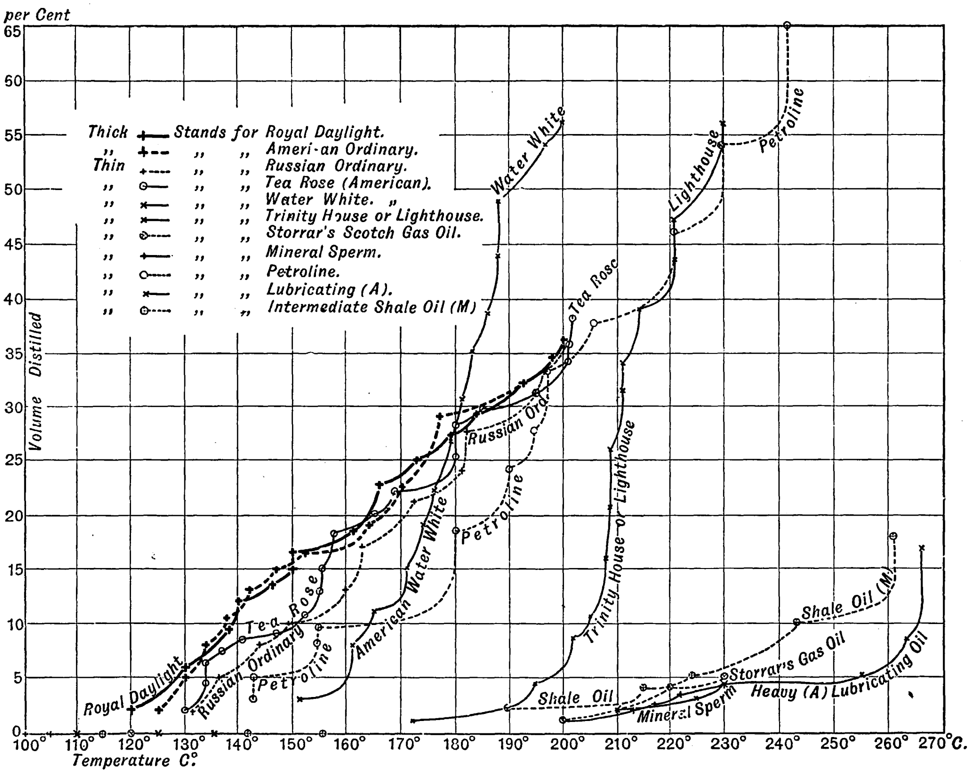
Bunsen burner, shielded from draughts. In one set of experiments the flask, O, containing the oil was completely immersed in an oil bath, B, and in another series the flask rested on the sand bath heated by the Bunsen flame. One thermometer, *a*, was kept immersed in the oil, the other, *b*, gave the temperature of the vapour at the neck of the flask, opposite the exit-tube leading to the condenser. In dealing with petroleum spirit, as benzoline, the more highly volatile hydrocarbon constituents, when driven over, might remain in the state of vapour at the ordinary temperature. Hence, ice-cold water was made to circulate round the exit tube, to cool and condense the products that came over. The tube

was slightly inclined, so that the distillate, as it condensed, trickled down the glass tube, and was allowed to drop into the graduated vessel, where its volume was measured. A current of air, forced into the bottom of the oil bath, B, bubbled up, and, acting like a stirrer, caused a continuous circulation, which maintained the temperature of the bath fairly uniform throughout.

As the sand and bath is heated very gradually, the temperature of the liquid oil in the flask was noted when boiling commenced vigorously, and the indications of both thermometers observed simultaneously.

Although the temperature of the liquid is steadily increased, the mercury in thermometer, *b*, frequently falls, when the oil vapour comes off slowly, and condenses on the bulb. Then the heating flame is slightly raised, in order to drive off more vapour, and so urge up the mercury in thermometer, *b*. The difference between the temperature of the liquid oil, as given by thermometer, *a*, and its vapour by *b*, varies with the rate of evaporation, and be-

FIG. 3.



FRACTIONAL DISTILLATION CURVES.

comes less and less as the temperature increases. This difference also depends on the size and shape of the flask, the quantity of oil used, and the heating flame, and other things which control the rate of evaporation.

With a homogeneous liquid, such as water, heated by a steady flame, this difference between the readings of *a* and *b* remains constant, since the water is at 100° C. or 212° F. all the time, but not so with petroleum.

In the case of oil, the distillation takes place in steps or stages, and in order to continue the evaporation, it is found necessary to increase the heating flame when distillation ceases at one temperature. Sometimes the rise in temperature takes place rapidly from one stage to the next, showing a very marked difference in the boiling points of the various constituents of the oil; at others, the changes are slow and gradual.

This property of oils may be more clearly seen by the diagram of distillation curves, Fig. 3, in which the heights of points represent the volume of oil distilled, and horizontal distances

the vapour temperatures (b) of the different fractions coming over. For instance, in the case of a simple substance, say pure water, the distillation curve would be a vertical straight line at 100° C. (212° Fahr.), indicating that under standard atmospheric pressure, water boils at 100° C. until the whole mass is evaporated, and the temperature does not go higher. Any increase in the heat applied merely causes more rapid boiling and distillation. Now, the more homogeneous an oil, the greater the proportion of it that will boil off within a given range of temperature; that is to say, the closer together are the boiling points of the various constituents, and, consequently, the more nearly will the distillation curve approach to a vertical straight line like that for pure water.

The curve for Broxburn Lighthouse or Trinity-house oil (Fig. 3) shows that this oil distils over within a comparatively limited range of temperature between 150° and 300° C.; that is, it distils between 302° and 572° Fahr., and so fulfils the Trinity-house conditions. On the other hand, "Royal Daylight," the ordinary burning oil supplied by the Anglo-American Oil Company, distils at a very low temperature (see Fig 3. and Table I., p. 964), and distils gradually, giving off fractions of oil which seem to increase regularly and uniformly both in boiling point and specific gravity, obtained through a wide range of temperature.

"Royal Daylight" oil boils about 140° C. (by thermometer a in liquid), and begins to distil about 160° C.; at 215° C. only 25 per cent. is distilled, at 230° C. 35 per cent., at 300° C. only 76 per cent., at 340° C. 82 per cent. On further urging the heating flame, there was a check on the evaporation indicated by the reading of thermometer b falling rapidly, although that of a was rising at 358° C., the utmost limit of the thermometer used. The fraction that distils at any one temperature varies slightly with the rate of heating. Evidently these fractional distillates consist of different hydrocarbons that are driven off at their various boiling points. By comparing these distillates we gain a pretty exact notion of the relative amounts of light and heavy products that are mixed together in the oil.

Take another American burning oil, known as water-white (see Fig. 3 and Table I., page 964). A large proportion of the vapour comes off with comparatively small change in the temperature. Thus, between 180° and 215° C., by thermometer a in liquid, 55 per cent., or more than half the oil, is given off. The boiling points of the constituents indicate that water-white oil approaches more closely to a substance of simple constitution, like water, than the other oils. Indeed, Mr. Boverton Redwood has pointed out that, at the refineries, the first and last portions which distil over—technically known as "tops" and "bottoms"—are rejected from "water-white," so that this oil contains fewer hydrocarbons, and is, consequently, of more uniform composition and simpler constitution than the usual run of ordinary kerosene oils.

From such an examination it follows that we must regard these refined petroleum oils of commerce as mixtures of a number of hydrocarbon distillates, each fraction having a more or less well-defined boiling point and specific gravity. Consequently, we may mix together an oil having a low flashing point and specific gravity with a very heavy oil, so that the mixture shall have a specific gravity of another very different substance. By fractional distillation we find the range of temperature within which all the oil distils, and obtain useful information regarding the volatility, boiling points, and amounts of the various constituents.

In any such distillation "cracking" may occur to the oil condensed near the exit tube, which falls back into the hot liquid and is decomposed into lighter products. Still, this action may be very slight, because when the condensation was reduced by immersing the neck of the flask in an oil-bath (Fig. 3), it was found that the per-centage of oil distilled under any given temperature (a) of the liquid, say 215° C. (Table I.) agreed exactly with that obtained by heating the oil in the same flask on the sand-bath without using the oil-bath.

Specific Heat.

When we come to consider in oil-engines the quantity of heat necessary to convert oil into vapour, in the vaporiser, we must know, 1st, the specific heat of the oil, in order to find the amount of heat required to raise the temperature of the oil in the liquid state; and 2nd, the latent heat of evaporation of the oil and oil mixture. By specific heat is meant the number of units of heat necessary to raise unit weight (1 lb.) of the liquid oil one degree in temperature. From experiments made on the burning oils between 10° C. and 20° C., I find the specific heat of these liquids about

0·4 to 0·5; as given in Table I., p. 964, are rough approximations.

LATENT HEAT.

The latent heat of evaporation of any burning oil is not a very definite quantity, because of the want of uniformity in the composition of these oils. Moreover, the more volatile fractions pass off readily, rendering it necessary to evaporate the whole of the oil taken, and even then the last dregs which have to be driven off are likely to leave a slight tarry or gummy deposit, so that for a given sample of oil only a mean or average value of the latent heat can be taken as compared with that of water. The figures obtained are given with every reservation as the result of preliminary experiments. Evaporating in the open air with heat applied by means of a steady flame, the latent heat of "Royal Daylight," appears to be about 1·09 times that of water, "Russolene" somewhat lower, and "Lighthouse" considerably greater. Now 1 lb. of water, at 100° C., will take 537 units of heat to convert the whole mass into steam at 100° C., hence the average latent heat of burning oils is about 1·12 × 537, that is, about 600 (lb. Centigrade) units or 1,100 British thermal units.

We must bear in mind that petroleum spirit evaporates very readily without leaving any deposit. When heat is steadily applied by a constant gas flame, it is found that a given quantity of heat evaporates nine times as much of petroleum spirit (sp. gr. ·680) as of water under the same conditions at atmospheric pressure, that is, the average latent heat of this spirit would appear to be only about one-ninth that of water. We must bear in mind that, for this comparison, we have to convert all the oil into vapour, inasmuch as a smaller amount of heat is required to evaporate the first half of the oil than for the heavier and less volatile portions left liquid to the last. Thus, the average latent heat of the heavier part of the petroleum spirit, towards the end of the evaporation, approaches the latent heat of water.

VOLUME OF PETROLEUM VAPOUR.

However, the spirit expands to about one-fifth the volume of vapour that water yields. Hence a given amount of heat can produce nine-fifths or 1·8 times the bulk of spirit vapour from petroleum spirit of specific gravity ·680 that it would of steam from water, at ordinary atmospheric pressure.

The increase in bulk from the liquid to the vapour, when taken at atmospheric pressure and standard temperature 0° C., is also much greater, in the case of light spirits, than of the heavier oil. With Victor Meyer's apparatus, and an air bath at 300° C., I find, for Russolene oil of specific gravity ·824, that the volume of air displaced by the amount of vapour formed at this temperature, when reduced to standard atmospheric pressure and 0° C., shows that the oil expands to about 310 times its bulk in changing into vapour. Experiments with various burning oils indicate that the bulk of the vapour formed is about 300 to 350 times the volume of the liquid at atmospheric pressure.

VAPORISATION OF OILS.

The *evaporation* of petroleum oil is usually effected, first, by heating the oil, and, at the same time, mechanically removing the vapour from the surface of the boiling liquor. In practice, the oil vapours are best carried off by superheated steam, which is allowed to escape from perforated pipes over the surface of the oil. The particles of oil vapour are kept hot by the steam, which carries them away mechanically, and so prevents the oil vapours condensing and falling back into the hotter liquid, to become "cracked" or decomposed. This plan is found to work better than that in which the vapours are removed by the ordinary vacuum pump and condensing coils.

I have determined the loss in weight of some heavy oils by prolonged heating at low temperatures, keeping the oils exposed to a slight air draught, and allowing free evaporation. Known weights of oil were taken in shallow platinum and nickel dishes, about three inches diameter across the top, and gently heated on a sand-bath by a very small, steady gas flame. Evaporation was encouraged in this way, the temperature being kept constant for an hour and a half. The proportion of volatile constituents present in three samples are given in Table II., p. 970.

Secondly, further evaporation is facilitated by churning or agitation, and exposure of a large surface of the oil to atmospheric air at the ordinary temperature.

A simple experiment will show the relative fractional evaporation by blowing a current of air through three samples of oil under exactly the same conditions. Take a known weight of Broxburn Lighthouse oil (specific gravity ·810) in a platinum dish. Connect a large flask by a piece of india-rubber tubing to a fine piece of glass tubing held in the oil Now blow the full of the flask of air very slowly, say in 15 minutes, so that it bubbles

TABLE II.—EVAPORATION.

Name of Sample.	Specific Gravity at 60° F. (15·5° C.).	Constant Temperature. (Centigrade.)	Time of Evaporation. (Hours.)	Per-centage Loss in Weight.	Total Per-centage Loss in Three Hours.
		Degrees.

		60 to 65	1·5	1·96	
		Steam Bath (95)	3	12·42	12·42

up through the oil without spurting, by allowing water to flow down into the flask, driving out and displacing the air. The loss in weight of the oil, due to evaporation, will be very small—perhaps about 0·3 per cent. Next, try exactly the same treatment on Royal Daylight oil (specific gravity ·797), and the loss is 2 per cent. Then take the same weight of benzoline (specific gravity ·700), and blow the same flask full of air through it in 15 minutes under the same conditions, and the loss may be about 25 per cent. By continued blowing of air through the benzoline, the greater part of it may be evaporated without the application of heat.

AIR CARBURETTORS.

There are various air-gas machines, or air-carburetting contrivances for saturating atmospheric air with highly inflammable petroleum vapour, by passing it through gasoline, benzoline, or petroleum spirit. The mechanical arrangements usually consist of (1) a blower, air-pump, or fan, driven by falling weights, like a clock, or otherwise, to force cool air over or through gasoline; and (2) the "carburettor," or chamber containing the gasoline in shallow trays, to have large surfaces of contact between the air and volatile liquid. Sometimes the gasoline is formed into fine spray by paddles or vanes rotating in a drum, through which the air is forced.

In these air-carburettors it is vapour, not gas, that is formed, and, like all vapour, it condenses when reduced in temperature or subjected to pressure. Moreover, the lighter constituents of the gasoline pass off first, leaving the heavy oil, cooled by loss of the

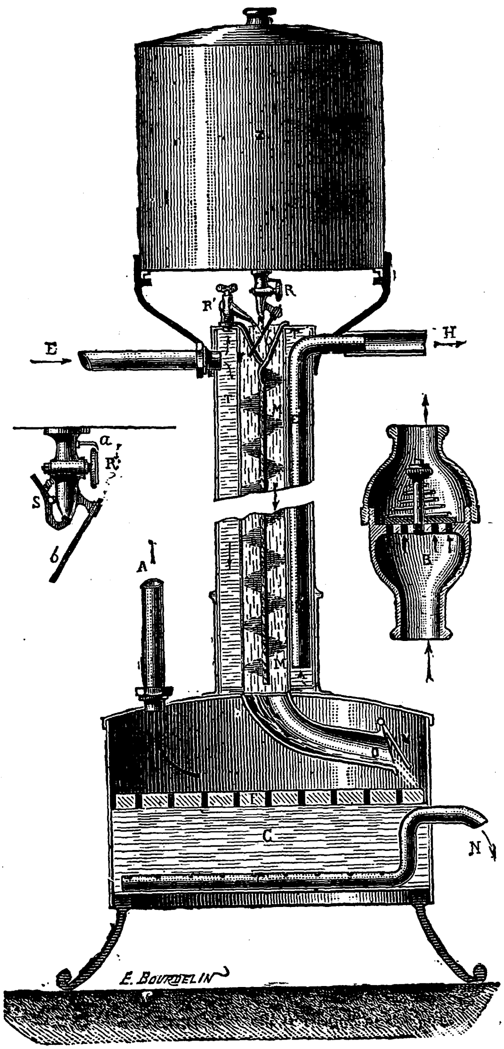

FIG. 4.—SIMPLEX CARBURETTOR.

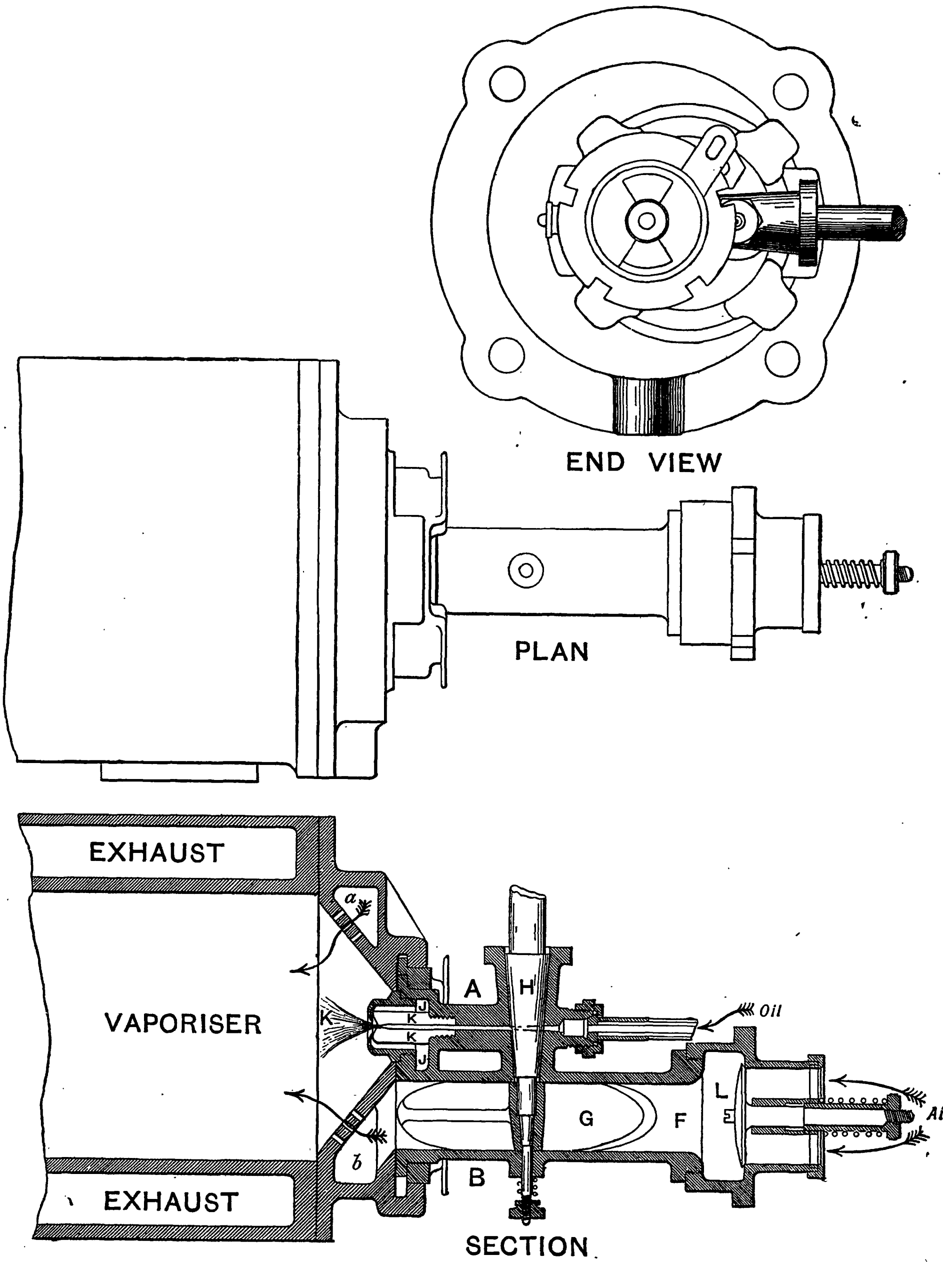
heat absorbed in evaporation, and this thick oily residue left behind is practically useless except as fuel.

Air charged with gasoline vapour is burned for lighting purposes, and sometimes used instead of gas in gas-engines.

FIG. 5.



PRIESTMAN SPRAY-MAKER.

SIMPLEX CARBURETTORS.

The Simplex Carburettor (Fig. 4, p. 970), employed with the gas-engine of Messrs. Delamare-Deboutteville and Malandin, of Rouen, consists of a cast-iron vessel surrounded by a water-jacket, T, through which the hot water passes from the cylinder-jacket by the pipe, E. A thin stream of oil trickles from the oil-tank, Z, by the graduated cock, R, and mingling with a

stream of hot water from the cocks, the mixture falls on the spiral horsehair brush, M. The oil vapour, water and oil, pass through D into the separating chamber, where the perforated cork float, F, prevents splashing, allows vapour, and not spray, to pass into the engine cylinder, by the pipe, A, and through the safety non-return valve, B. The water overflows by the siphon, N, and carries with it the mineral and vegetable constituents of the refuse oil, which would tend to produce incrustation, if burned in the engine cylinder.

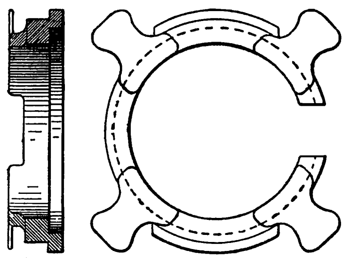
The highly volatile hydrocarbons in gasoline and benzoline used in all these air carburettors are very dangerous, and I do not recommend their use with gas engines.

Priestman Spray Maker and Vaporiser.

However, through the kindness of Messrs. Priestman, we have on the table an apparatus, by means of which the heavy and safe burning oils of commerce, as "Royal Daylight" and "Lighthouse" oil, may be finely divided up into spray, heated, vaporised, and mixed with air, ready for use, before entering the cylinder of the internal combustion engine.

In the Priestman spray-maker and vaporiser (Fig. 5, p. 971), specially designed to prepare ordinary burning oils, so as to avoid clogging in the engine, we have, as the result of many careful and laborious trials, a neat and simple combination of the two methods of treating the oil, namely—(1) spraying the oil, and then (2) evaporating the exceedingly fine spray cloud by heat. These functions are performed by the spray maker and the vaporiser shown in section (Fig. 5), joined together at A B, and may be readily separated by the wing-nut (Fig. 6), when

Fig. 6.

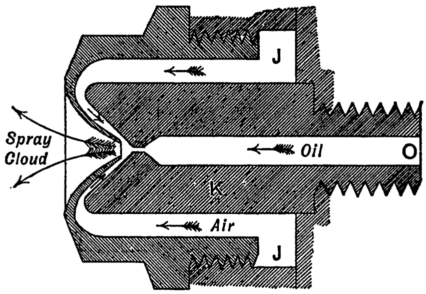


Wing Nut.

it is desired to examine the passages and spraying-nozzle, K, Fig. 5. This nozzle, K, being the most important organ in the engine, is shown in Fig. 7, nearly twice actual size. The mouth-piece is re-entrant and conical, so that the air coming from the annular space, J, turns through more than a right-angle, and converges to the point of issue of the oil-jet. The air, slightly compressed, from 8 lbs. to 12 or 14 lbs. per square inch above atmospheric pressure in top of the oil-cistern of the engine, enters the passage, J, to the nozzle, and meets the oil which has been forced by the same pressure of air-pump from the bottom of the oil-cistern, through another pipe and plug, H, Fig. 5, to the passage, O, in K, Fig. 7. The oil-jet is thus completely broken up by the air forced upon it, and comes out of the mouth-piece in the form of a hollow cone or spray-cloud of particles so finely divided as to be suspended in the air.

A simple experiment will illustrate this action. Turn off the air supply, and the small, unsprayed oil-jet is forced out by the pump in

Fig. 7.



Priestman Spraying Nozzle.

an unbroken stream, which is not inflammable, and is not ignited by the flame of the burning taper touching it.

Next, turn on the air-supply to nozzle. This air meets the oil-jet at the same pressure, and thoroughly breaks it into fine spray. The fine particles of oil-spray so formed are intimately mixed with the air, and rise in a cloud, and can be readily ignited, burning with a beautiful bright flame, no smoke being formed. (Experiment shown).

On the other hand, if the quantity or pressure of air be reduced, so that the oil-jet is not completely broken up, you will see some of the heavy particles of oil falling below the spray cloud, and when ignited it burns with a smoky flame.

Again, turn on the air at proper pressure, blowing across the oil-jet, and, you observe, so finely divided is the oil, and intimately mixed with air, that it remains suspended,

and when ignited, burns with a beautiful clear flame, showing complete combustion. (Experiment shown.)

In the working of the oil engine the spray-cloud is heated in the vaporiser, Fig. 5, by the exhaust gases. These hot products of combustion from the previous charge are led around the vaporiser before being allowed to escape, and heat the mixture of oil-spray and air inside the vaporiser to about 170° or 300° Fahr., and thus convert the greater part of the finely divided oil into vapour. Besides the air forced from the oil cistern to the nozzle for spraying the oil, an additional supply of fresh air is drawn from the annular passage, *a*, *b*, Fig. 5, and mixing with the heated spray-cloud and air carries it forward into the oil engine cylinder, where the mixture does duty in just the same way as ordinary coal gas and air in the gas-engine cylinder.

FIG. 8.

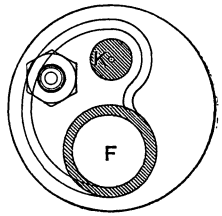
OIL-PLUG.

Experiment shows that, in order to ensure complete combustion, the exact proportions of oil and air must be maintained whatever be the strength of the charge required, and every spraymaker must be carefully tested, adjusted, and the supply passages graduated for different conditions of running, in order to completely control the action of the engine.

The supply of oil entering the spraymaker is regulated by the cock or plug, H, Figs. 5 and 8, worked by the engine governor. In this oil-plug there is a small tapering hole, Fig. 5, widening into a **V**-shaped notch on one side, Fig. 8. By slightly turning this plug, the supply of oil that passes through it can be regulated to a nicety, the wide part of the **V**-notch being always covered, so that the oil supply enters the plug only at the sharp edge of the notch, and it can never be completely shut off while the engine is running. On the same spindle, H, Fig. 5, p. 971, there is fitted a wing throttle-valve, G, which controls the amount of auxiliary air entering by the passage, F, Figs. 5 and 9. The throttle valve passage is carefully adjusted, so that the air passing through it will always be in the right proportion to the oil admitted by the **V**-notch in the plug, to form an explosive mixture, no matter how the spindle is turned by the governor at the normal speed of the engine. Consequently the amount of oil admitted is diminished or increased with the exact proportion of air, so as to form a strong explosive charge, or a weak one, according to the work being done by the engine.

When the engine-speed is very slow, far below the normal working speed, the additional air may not be drawn in rapidly enough, and the right composition of mixture for complete combustion may not be obtained,

FIG. 9.



Section through A.B.

with the results that the oil will not be all burned. The additional air, drawn into the cylinder by the motor-piston, enters the end of the vaporiser through the holes at *a*, *b*, as shown in Fig. 5 by the arrows. Before coming to the passage F, Fig. 5, through the non-return valve L, the air is cleansed of dust and grit, by passing through layers of cotton wool fixed on gauze, at the end of the air-passage, which can be closed by rotary plate or shutter. The air drawn into the oil cistern by the air pump, and used in the spraying nozzle, must also pass through layers of cotton wool, to cleanse it of dust and dirt, because the passages are very fine, and could be very easily choked up.

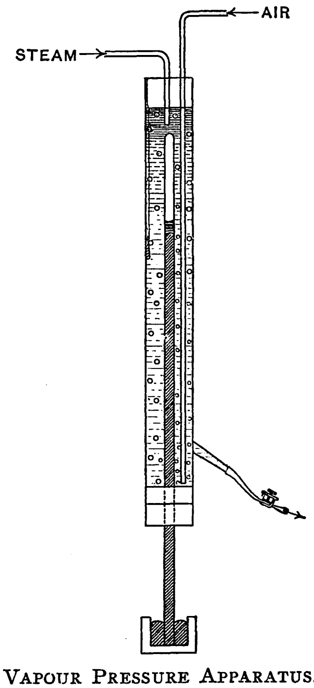
In fact, any oil-spray making and vaporising arrangement works under very critical conditions, when supplying oil vapour in the place of coal gas to the internal com-

bustion engine. The oil must be taken direct from its cistern, thoroughly mixed with the right proportion of air, heated to a nicety, and passed into the cylinder, ready for ignition, at the rate, in some engines, of two to four separate charges per second; so that, unless the arrangement for dealing with the heavy oils is correct, and works with unerring precision, there is a tendency to clog in the working parts of the engine. Many difficulties are also presented by the complex and varied character of the different burning oils and intermediate oils at present available for use in the cylinder of the common oil engine.

PRESSURE OF PETROLEUM VAPOURS.

In order to gain some exact notion regarding the behaviour of these oil vapours, when

FIG. 10.



VAPOUR PRESSURE APPARATUS.

compressed in the engine cylinder, we are led to find the relation between their pressure and temperature.

The vapour pressure of different oils, at temperatures between freezing point and boiling point of water, may be measured by means of the apparatus, Fig. 10, which consists of a barometer tube, thoroughly dried inside and filled with clean mercury. About ½ cubic centimetre of the oil is introduced above the mercury into the Torricellian vacuum at the top of the tube, which stands in a long deep trough of mercury. The upper part of the barometer tube is surrounded with a bath, which may be changed in temperature.

We may start with the bath much below the freezing point of water by adding a mixture of snow and salt. Then, by draining off this freezing mixture and adding fresh water, the temperature is very gradually raised, say to 0° C. Above 0° C., the water bath is gradually heated by steam passed into it, whilst a current of air is forced into the bottom of the bath, and allowed to bubble up, thus causing a continuous circulation, and maintaining the temperature of the bath fairly uniform throughout.

After the temperature of the bath has been kept constant for some time, note this temperature and the height of the mercury column from the surface in the trough to that of the oil above, as compared with the standard barometer.

Numerous heating and cooling readings should be taken with each sample of oil, and, as a check on the best rate of heating, the bath frequently kept at the same temperature for two or three minutes, to see whether the oil vapour had at first attained its full pressure, corresponding to the temperature indicated by the thermometer in the bath.

The observed height of the mercury in the standard barometer and in the tube containing the petroleum vapour are reduced to what they would be at 0° C., the parts of the tube in and out of the bath being taken separately. The difference between the corrected heights of mercury in the tube and standard barometer may be taken as a measure of the pressure with which the petroleum vapour pushed down the mercury column.

The absolute pressures of the vapours, from two typical samples of burning oils—"American Royal Daylight" and "Tea Rose" (see Table I., p. 964), expressed in millimetres of mercury, are shown in Table III., p. 975.

The rate of change in the pressure, due to increase of temperature, can be seen more readily from the curves (Fig. 11) obtained by plotting the results of several sets of corrected pressures, with the corresponding temperatures, on squared paper. The curve for water vapour is shown merely for the sake of comparison; and it is seen the pressure of water vapour is much higher than any of these oils give. The regularity of these curves is striking, and shows a gradual steady increase in the vapour pressure as the temperature rises. The same quantity of oil—about two cubic centi-

TABLE III.—PRESSURE OF PETROLEUM VAPOUR.

Temperature. (Centigrade.)	Vapour Pressure.

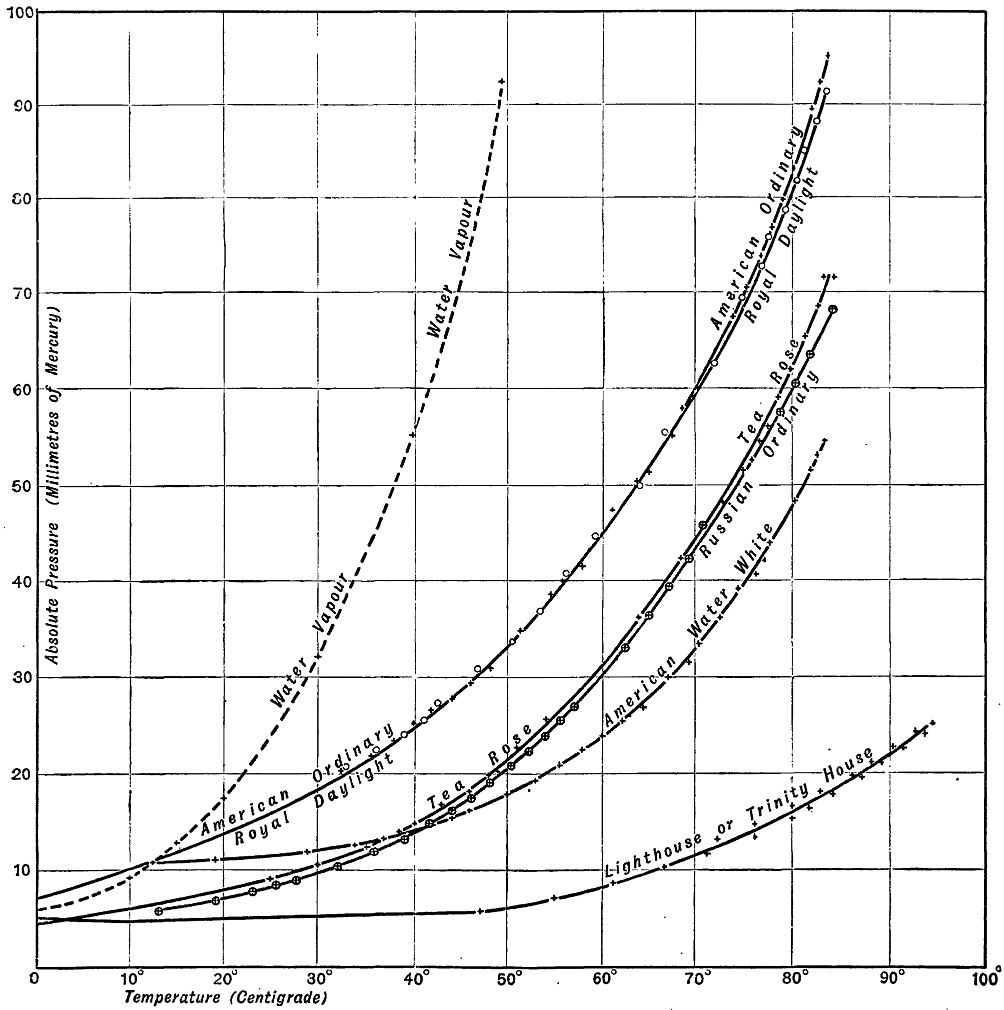
50	32·7	21·1
55	38·1	25·0

metres—was used in each case above 20° C.; and the recent values obtained for pressures below this temperature are given in Table III.

"Royal Daylight" and "American Ordinary" practically agree, and give higher pressures than any of the other samples of kerosene.

It would appear from these curves, considered along with those from the fractional distillation, that the more volatile constituents in these two samples of oil are the same—that is to say, the "tops" are the same in both. "Tea Rose" closely agrees with the "Russian Ordinary," but contains a larger proportion of the light products. On the other hand, "Water-white" is quite distinct in its character from the other samples of kerosene, and comes nearer that of "Lighthouse Oil," which, however, gives very much lower pressure, only

FIG. 11.

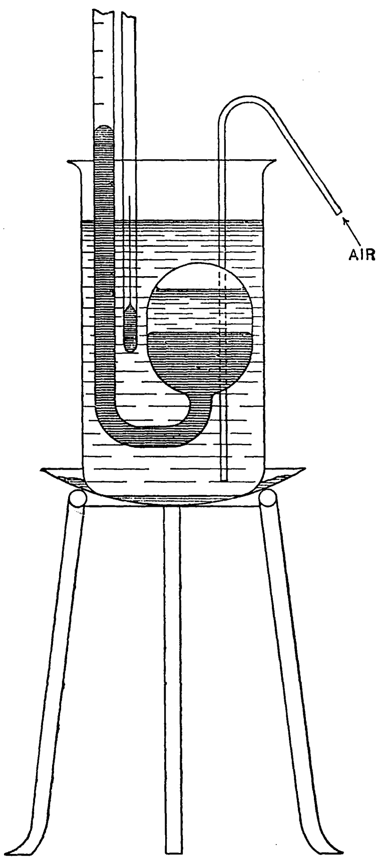


PRESSURE AND TEMPERATURE OF PETROLEUM VAPOURS.

$\frac{1}{30}$th of an atmosphere, when heated up to 95° C.

In order to investigate the pressure of these oil vapours at temperatures above the boiling point of water, a simple arrangement consists of a piece of graduated glass tube, bent into U-shape, with a bulb blown on the end, as shown in Fig. 12. The graduated tube is about a yard long, and 5 millimetres bore. The bulb is elongated egg-shaped, of 30 cubic centimetres capacity, average diameter 30 millimetres, and length 40 millimetres. Having

FIG. 12.



OIL-VAPOUR PRESSURE APPARATUS.

thoroughly cleaned and dried the bulb, it was filled with mercury, and 7 cubic centimetres of the oil was introdnced in every case, occupying about one-fourth of the bulb. The quantity of mercury was adjusted to stand at the same level in the bulb and tube when put into the bath of glycerine. The height of the standard barometer was observed, and the temperature of the room and bath noted. This bath was gradually heated by a Bunsen burner, and stirred with a current of air, which kept the whole mass of glycerine at a uniform temperature. As the temperature of the glass rose, the glass bulb and tube were first heated and expanded; after a certain interval of time, the mercury and oil took up the same temperature, and expanded accordingly. Thus, the apparent rise of mercury in the tube was the net result of the expansion of the oil and mercury diminished by the expansion of the glass. This was found to be 0·5 millimetre for every 1° C. rise in temperature. The co-efficient of expansion of mercury is 0.00018, and that of petroleum varies from ·0008 to ·0009 for 1° C. Allowance could thus be made for the rise of the mercury due to liquid expansion, apart from vapour pressure.

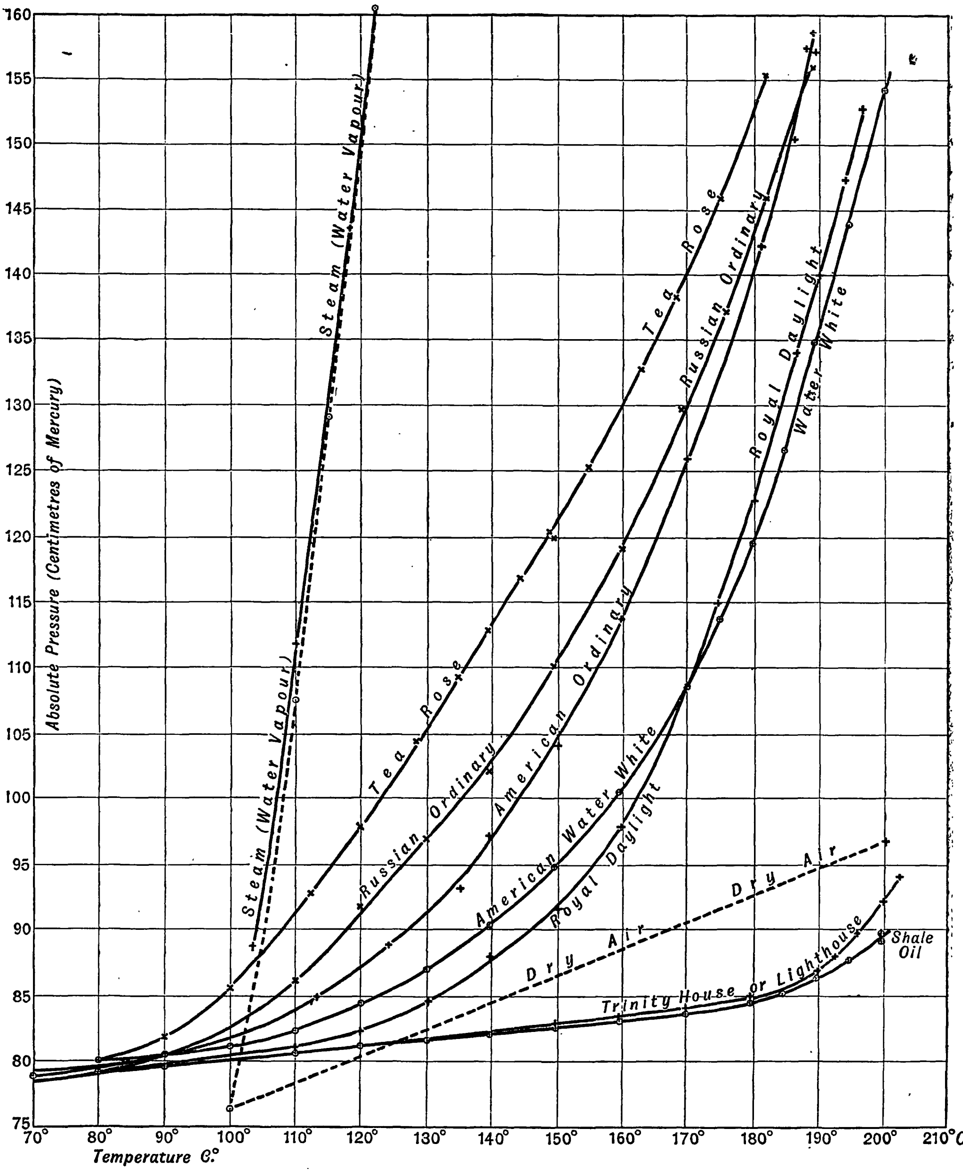
As the bath was gradually heated, the difference of level of the mercury in the tube and bulb was observed, and the corresponding temperature of the bath. Before taking a reading, the bath was kept at the same temperature for some time, and readings were taken every 5° C. Taking the mean temperature of the mercury, the observed height of the column was reduced to what it would be at 0° C. The greatest change in level of the mercury in the bulb varied from 16 to 18 millimetres, corresponding to a change of level of mercury in the pressure tube of 840 millimetres. The range was limited by the length of our graduated tube, although I did not care to push the glycerine much above 200° C.

In order to verify my work, I tried water instead of oil, and obtained the curve shown in Fig. 13 (p. 977), which above 100° C., practically coincides with that obtained by plotting Regnault's figures. Thus encouraged, and by numerous experiments, in taking oft-repeated heating and cooling readings for every sample of the kerosene, and some heavy oils, we obtained the results which, when reduced and corrected, as indicated above, and plotted on squared paper, give the curves shown in Fig. 13.

My experiments prove that notwithstanding the complex and varied character of the different oils examined, *the law according to which the pressure of petroleum vapour varies with temperature is represented by a regular curve for each oil.*

Moreover, the relative steepness of these curves is somewhat similar to that obtained by the fractional distillation curves of these oils. The petroleum vapour pressure is seen to be less than that of steam, but gradually approaching it as the oils become more volatile, until, in

FIG. 13.



PRESSURE AND TEMPERATURE OF PETROLEUM VAPOURS.

the case of benzoline and petroleum spirit, the pressure (Fig. 14, p. 978) exceeds that of steam.

Several other properties of these oils we shall discuss in this course of lectures when considering the different

USES OF PETROLEUM FOR POWER PURPOSES.

To-night we have here on the table a number of petroleum oils, ranging from benzoline up to the heavy residuum liquid. These are all used, in one way or another, in prime motors, thus :—

1st. *Petroleum Spirit, or Naphtha*, such as benzolene, which comes off as inflammable vapour at ordinary temperatures, and flashes at a temperature below 73° Fahr. (Abel close test), is wisely regarded by Act of Parliament as dangerous spirit, and is specially restricted, as regards its transport, storage, and use in this country. This naphtha, or

petroleum spirit, may be used exactly in the same way, and instead of steam, as evaporating and working agent in the type of engine precisely similar to a steam-engine, in Yarrow's spirit launch, where the naphtha-vapour is completely enclosed, condensed, and used over again.

Similar naphtha-vapour engines are fitted in small boats or spirit-launches, now built by Messrs. Escher Wyss and Co., of Zürich. Some of these launches are made of aluminium. One part of the naphtha is used as fuel to evaporate the working portion, and the oil vapour takes the place of steam as the working fluid in the engine. The naphtha used is dangerous, and not readily procured. It floats on water, and serious accidents and fires have occurred in America with this type of motor in small boats.

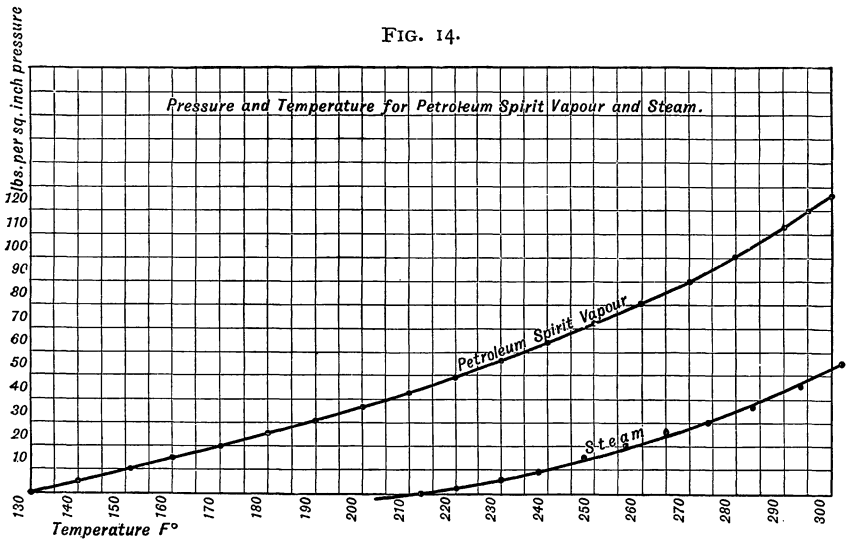
There is also a great temptation to use benzoline in the internal combustion engine, because it is easily vaporised without deposit, and burns readily.

In the petroleum spirit engines there are also many air-carburetting and heating devices, to evaporate the highly volatile hydrocarbons, which make up the lighter products of petroleum, known as naphtha or benzoline, gasoline, and shale spirit.

However, the terrible danger and risk in storage and handling of highly inflammable hydrocarbons, prohibit their common use for prime motors.

2nd. *Burning Oils.*—We find the lamp or

FIG. 14.



lighting oils, converted into vapour at low temperature, are being largely used instead of coal gas, as fuel and working agent in modern oil engines, which are rapidly replacing small gas and steam engines, because they are self-contained, and the petroleum oil can be obtained at a low price in almost any country village.

3rd. The heavy intermediate shale-oil, or partially refined petroleum, may be converted into real gas, not vapour, at high temperature, in an oil-gas producer, and this oil-gas, when cooled, is used instead of lighting gas in the gas engine.

4th. Mineral lubricating oils are largely used as lubricants in machinery, and I shall discuss the properties, tests, and uses of these oils in a subsequent lecture.

5th. There still remains behind the heavy refuse which was once considered to be useless for prime motors, inasmuch as these oils—common coal-tar, green oil, blast furnace oil, American residuum, and Russian astatki—cannot be made into true permanent oil-gas. In many places we find such oils used instead of coals, and injected as fuel with steam under steam boilers and in forges, where this liquid fuel is cheap and plentiful, and the price of coal too high.

Consequently, we are able to find a use in prime motors for nearly all the products which are obtained from the distillation of either the bituminous shale, to be had in abundance in this country, or from the petroleum oils which exist in the liquid state in the earth's crust.

Miscellaneous.

CHICAGO EXHIBITION.

The following statistical notes of the World's Fair Buildings at Chicago are given in an article by Mr. H. C. Bunner in *Scribner's Magazine* for the current month. These figures are approximately correct, within a foot or so; fractions are suppressed for the sake of simplicity; and allowance must be made for slight alterations in plan:—

The grounds are a little less than a mile-and-a-half in length. In width they are about a third of a mile at the narrow end, and about four-fifths of a mile at the broad or south end. Speaking roughly, this is about equivalent to as much of the lower end of New York City as would be separated from the upper portion by a line drawn from the foot of Canal-street and North River to the foot of Rutgers-street and East River. They contain more than half a thousand acres, exclusive of the Midway Plaisance, an annex running eastward behind the Women's Pavilion.

The Main Court, Plaza, or Cour d'Honneur is a quadrangle 2,000 by 700 feet. It contains the Great Basin, 1,100 by 350 feet; the MacMonnies Fountain, the centre-piece of a basin 150 feet in diameter; and terminates at the lake end in the Peristyle designed by Mr. C. B. Atwood, which is 60 feet high and is composed of four rows of pillars.

The Manufactures and Liberal Arts Building is 1,687 by 787 feet in size. It covers about thirty-one acres. The great main roof covers an area 1,400 by 385 feet, and has an extreme height of 210 feet. This is between 55 and 60 feet higher than the Great Arch of the Machinery Building in the recent Paris Exposition. It is only 10 feet less in height than the great chimney of the New York Steam-Heating Company. It is just 6 feet lower than the top of the spire of Grace Church, New York. It is 11 feet lower than the Bunker-hill shaft at Boston. It would hold the Vendome column mounted on a 74 foot pedestal. The seating capacity of the building is estimated at over 200,000 people. St. Peter's at Rome holds about 54,000, St. Paul's in London less than 26,000, and the Metropolitan Opera-house in New York has a capacity of 5,000 people. The entrances to this building are 40 feet wide by 80 eet high. Its ground plan is much more than twice the size of that of the Pyramid of Cheops. It is the better part of a 100 feet longer than the main span of the Brooklyn Bridge. It is nearly two and one-half times as long and more than two and one-half times as wide as the Capitol at Washington. The architect is Mr. George B. Post, of New York.

The Agricultural Building is 800 by 500 feet. Its central dome is 130 feet in height and 100 in diameter. The corner domes are between 90 and 100 feet high. The cornice-line is 65 feet high.* Messrs. McKim, Meade, and White are the architects. The statuary adornments of the building are designed by Mr. Philip Martiny. The annex to this building is 550 by 300 feet.

The Machinery Hall is 846 by 492 feet. Its annex 550 by 490 feet. These dimensions do not include boiler-house, machine-house, &c. The architects are Messrs. Peabody and Stearns, of Boston.

The Administration Building is 260 feet square. The dome is 275 feet high externally; the interna dome is 190 feet in height. That is, it is about as high on the outside as Trinity Church spire in New York. The dome of the Capitol at Washington is 287 feet in height, and internally considerably smaller than that of this building. Mr. Richard M. Hunt, of New York, is the architect; Mr. Kar Bitter, the statuary.

The Hall of Mines and Mining is 700 by 300 feet, and the architect is Mr. S. S. Beman, of Chicago.

The Electrical Building is 690 by 345 feet. The four corner towers are 169 feet high. The longitudinal nave is 115 feet wide by 114 feet high. Messrs. Van Brunt and Howe, of Kansas City, are the architects.

The Transportation Building is 960 by 256 feet, with a one-storey annex covering about nine acres The cupola is 165 feet in height. Messrs. Adler and Sullivan, of Chicago, are the architects.

The Horticultural Building is 998 by 250 feet; The dome is 187 feet in diameter and 113 feet high Mr. W. L. B. Jenny, of Chicago, is the architect.

The Women's Pavilion is 388 by 199 feet. The architect is Miss Sophia G. Hayden, of Chicago.

The Building of the Institute of Fine Arts (permanent) is 500 by 320 feet, with a dome 125 feet high. The architect is Mr. C. B. Atwood.

The Fisheries Building is over 1,000 feet in extreme length, the main building being 365 by 165 feet, flanked by two circular pavilions, each 135 feet in diameter, connected by arcades. Its water capacity is 140,000 gallons, exclusive of reservoirs. The architect is Mr. Henry Ives Cobb.

Other buildings are the Dairy Building, 200 by 95 feet; the Government Building, 415 by 345 feet; the Forestry Building, 500 by 200 feet; the Stock Pavilion, 440 by 280 feet; and the Illinois Building, 450 by 160 feet.

CHICAGO EXHIBITION FINANCE.

A budget of the assets and liabilities of the World's Fair up to October 1 is being prepared by the auditor, Mr. Ackermann. The following particulars of the

* By general agreement among the architects, 65 feet is accepted as the standard height of the main façade in most of the buildings.

financial situation have been published. It is estimated that the gate returns from May 1 to Nov. 1 will amount to £2,400,000, and that no less than £1,000,000 will be realised for concessions. The total income is set down at little less than £8,000,000 sterling. The items are as follows:—

Capital Stock	£1,120,000
City bonds	1,000,000
Exposition bonds	900,000
Congressional appropriation (5,000,000 souvenir half-dollars)	500,000
Premium on souvenirs	500,000
Gate receipts	2,400,000
Salvage	200,000
Ceremonies	30,000
Admissions to May 1	70,000
Total	£6,620,000

To this is to be added the sum realised from the concessions arranged by the Ways and Means Committee. The figures given are as follows:—

Restaurants	£500,000
Intramural railroad	60,000
Water transportation	45,000
Barre sliding railway, American glassware, street in Cairo, street in Constantinople, Eskimo village, Algerian and Tunisian village, Morocco village, Chinese village and theatre, Japanese bazaar, and other foreign attractions	120,000
Mineral water springs	60,000
Panoramas: Burmese Alps and Kilauea; Captive balloon; Hagenbeck's animal show, and other similar attractions	60,000
Cocoa and chocolate	15,000
Music halls	40,000
Miscellaneous concessions: Pop corn, glassware, pea nuts, guide books, confectionery, soda water, flowers, wheel-chairs, gum, and other like privileges	100,000
Total	£1,000,000
Preliminary receipts	6,620,000
Grand total	£7,620,000

The liabilities are estimated as follows:—

Capital stock	£1,120,000
City bonds	1,000,000
Exposition bonds	800,000
Construction	3,800,000
Operation	800,000
Total	£7,520,000

Obituary.

H. W. Freeland.—Mr. Humphrey William Freeland, who died on Sunday night, 2nd inst., at his residence in Chichester (aged 78), had been a member of the Society of Arts since 1867, and was an occasional attendant and speaker in the discussions at the evening meetings. Mr. Freeland represented Chichester in the House of Commons from 1859 until 1861, and during the Russo-Turkish war he was appointed a member of the Stafford-house Committee. He published several volumes, consisting of lectures, poems, and translations.

General Notes.

Kerosene Trade at Canton.—The following note respecting the kerosene trade at Canton, extracted from the last annual report of Mr. T. Watters, her Majesty's Consul at that place, is taken from the *Board of Trade Journal*:—"The importation of kerosene at Canton rose from 25,790 gallons in 1890 to 4,639,971 gallons in 1891. Of the latter amount 4,283,171 gallons were American and the rest Russian. The value at Canton of all the kerosene imported was about £144,392. This oil seems to be supplanting the native vegetable oils, not only at the large towns near the coasts, but also in the interior. Last year so much as 3,129,480 gallons were sent up country from Canton under transit pass. The junks imported direct from Hong-Kong to the various small ports, according to Kowloon Customs, 4,636,383 gallons. This shows a falling off to the extent of 2,178,066 gallons as compared with 1890. The diminished importation by junk merely indicates the transfer of so much kerosene to steamers and the Imperial Maritime Customs."

Exhibition at Rome, 1895.—An organising Committee has been appointed at Rome for the purpose of arranging for a National Italian Exhibition, to be held in that city in 1895. The Department of Fine Arts and Electricity, however, are not to be confined to the country, but will be made International.

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

Journal of the Society of Arts.

No. 2,083. Vol. XL.

FRIDAY, OCTOBER 21, 1892.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Chicago Exhibition, 1893.

VIEW OF EXHIBITION.

With this week's number of the *Journal* is issued a new view of the buildings and grounds, upon which are shown recent additions and alterations, as well as a plan of the Midway Plaisance.

MEETING OF THE ROYAL COMMISSION.

A meeting of the Royal Commission was held on Wednesday, 19th inst. Present: Sir Richard Webster, Q.C., M.P., in the chair, Sir Frederick Abel, K.C.B., D.C.L., D.Sc., F.R.S., Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D., Sir Edward Birkbeck, Bart., Sir Edward Braddon, K.C.M.G., Sir Frederick Bramwell, Bart, D.C.L., F.R.S., Michael Carteighe, Sir George Hayter Chubb, Sir Henry Doulton, James Dredge, Professor Francis Elgar, LL.D., Sir Douglas Galton, K.C.B., D.C.L., F.R.S., Sir Edward Harland, Bart., M.P., Walter H. Harris, Charles Malcolm Kennedy, C.B., John O'Connor, William Henry Preece, F.R.S., Sir Owen Roberts, M.A., D.C.L., F.S.A., Sir Albert K. Rollit, LL.D., M.P., with Sir Henry Trueman Wood, M.A., Secretary.

EXECUTIVE COMMITEEE.

A meeting of the Executive Committee was held on Wednesday, 19th inst. Present:—Sir Richard Webster, Q.C., M.P., in the chair; Sir Frederick Abel, K.C.B., F.R.S., Sir Frederick Bramwell, Bart., D.C.L., Sir George Hayter Chubb, Sir Henry Doulton, James Dredge, Sir Douglas Galton, K.C.B., D.C.L., F.R.S., John O'Connor, W. H. Preece, F.R.S., with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

REPORT ON THE PROGRESS OF WORK.

By Colonel Hayes Sadler.

[*Concluded from p.* 960.]

Concessions.

The concessions already arranged include the Tower of Babel, 400 feet high, with a diameter at the base of 100 feet, which will stand in the centre of the Midway Plaisance; the exhibit of Irish Cottage Industries at the end nearest the Women's Building; the Bohemian Glass Company and the Libby Glass Company of Toledo, Ohio; Japanese bazaars, covering a space of about 225 feet square; the animal show of Carl Hagenbeck, of Hambnrg; Settlement of the South Sea Islands, including the Fijis, Samoan, Philippine, Solomon, Java, Borneo, and the Society Islands; a natatorium, 190 feet by 250 feet, and, in connection therewith, a Viennese *café* and bakery; panorama of the Bernese Alps; a German village, with representations of the houses of the Bavarian Mountains, of the Black Forest, the Hessian and Altenburg House and other typical German homes, including a German ethnological museum; a Turkish village, being the representation of one of the old streets of Stamboul, in connection with which are displayed the manufactures of Turkey, including Syria, also typical dances and other entertainments peculiar to the country; a minaret tower, from which will be heard daily the Muezzin call to prayer; Moorish palace, in which will be many illusions, camera obscura, &c., with a restaurant capable of seating 1,000 people, one of the great attractions of this building being an exhibit of 1,000,000 dollars in gold coins; street in Cairo, being a representation of the old Egyptian city, attached to which will also be mosques, dancing-halls, and many famous curiosities; Tunisian and Algerian section, showing the typical people of North Africa, their merchandise, as well as artisans at work; Ferris wheel, a wheel 250 feet in diameter swung on an axle, the largest steel casting ever made, resting upon towers 135 feet high, cars are hung at different points on the perimeter, to contain people who make the complete circuit of 250 feet, the weight of this entire revolving mass being 2,300 tons; ice railway, a practical winter exhibit, including a slide with an accumulation of ice thereon formed by artificial refrigeration; Pompeiian house, a complete representation, including

works of art; panorama of the volcano of Kilanea; section of Morocco, similar to sections of other countries; Chinese section, including a tea house, village, and theatre; captive balloon, with capacity for carrying 28 people to a height of 1,500 feet; section of old Vienna, Austrian village; East India, typical section, showing people, customs, manners, and merchandise; Dahomey village, 60 natives of both sexes, including several chiefs.

Constructions in view of the Exhibition.

The handsome city of Chicago, risen as it has in so marvellously short a time, containing now 1,500,000 inhabitants, and covering more than 180 square miles, will, with its building, parks, and boulevards, so often described, constitute in itself an attraction to visitors, while the numerous new constructions which have been and are being erected in connection with and in view of the Exhibition will add much to its imposing appearance. The new Art Institute, which is now in course of erection in the heart of the city, and is intended to be a permanent building, is fast rising above the ground; the foundations are complete, and the walls as far as the second floor at the northern end are already up, a large number of hands being employed; it will be finished in time for the opening in May next. Three-quarters of a mile further south, on the borders of the lake, the Illinois Central Railway Company are building a new passenger station, which, in point of architecture, conveniences, and solidity will, it is thought, be the finest in the country, if not in the world. As in all constructions on the borders of the lake, the foundations are on piles, which, in this instance, are driven 70 feet below the surface by a 4,000 lb. hammer till they reach the lower stratum of hard clay. The piers will be of stone, on which steel columns will support the structure. The three lower stories will be of pink granite, and the upper ones of Pompeiian brick and terra-cotta; the tower will be 200 feet high, and the area of the waiting room 150 feet by 100 feet. It will be finished by May next, and will cost £200,000. This railway company is raising its tracks in the neighbourhood of Jackson-park, beginning the ascent at Forty-seventh Street, on an embankment 130 feet wide at the top, which will obviate the dangers now existing of level crossings. The work will be completed by the winter. Trains run every few minutes alongside the lake to the Exhibition grounds, stopping at suburban stations half-a-mile apart. Steamers will also ply from the lake front, horse and cable cars now run direct to the Exhibition, while the new elevated railroad starting from Congress-street will be finished as far as the grounds. Drinking water at the Exhibition will be supplied from the beautifully clear springs of Wankesha, about 90 miles distant. In a short time the general water supply of the city, which has lately been far from what might be desired, will be derived from the new crib, through a tunnel four miles out into the lake, where, it is said, the water is quite free from sewerage contamination. A great deal has already been done in the way of paving streets, cleansing alleys, and generally cleaning and improving the city. Much has also been done towards completing the city boulevard system, which will ultimately run entirely round the city, and, with the numerous and extensive parks, afford drives of nearly 100 miles in length. Many hotels and boarding-houses, in different parts of the city, have been put up, with a view to accommodate the numerous visitors who, it is expected, will flock next year to Chicago, and others are commenced or projected, especially in the neighbourhood of Jackson-park, where quite a new city has sprung up; and it is thought that 150,000 strangers will thus be accommodated.

Financial Position.

The total receipts up to July 31 amounted to £1,937,864, derived from the following sources: capital stock, £999,475; appropriation by the city of Chicago, £900,000; interest on deposits, £10,039; miscellaneous receipts, £14,792; and liabilities, £13,568. The disbursements for preliminary organisation expenses amounted to £18,156, and up to the end of July £202,850 had been expended in general expenses, and £1,306,128 for the various disbursements which came under the head of constructive expenditure, making a total of £1,527,134, and leaving a balance in hand of £410,750.

The constructive expenditure in July amounted to £147,283, and the administrative or general expenses to £14,818, a total for the month of £161,101. The force employed by the direction that month numbered 1,743 persons, and the compensation paid was £29,315. The whole force employed on the grounds by the administration and contractors was about 8,400 hands.

The total contracts let reach to the figure of

£1,874,193, of which sum £973,056 was paid to the end of July, leaving a balance payable of £901,137. The contracts for the 13 principal buildings constructed at the expense of the Commission amount to £1,206,228, of which £796,820 has been paid. The cost is distributed as follows :—

	£
Mines and Mining Building	52,582
Electricity Building	84,900
Galleries of Fine Arts	98,528
Manufactures and Liberal Arts Building	306,760
Transportation Building	57,893
Machinery Hall	227,735
Administration Buildings	95,569
Agricultural	136,753
Forestry	14,623
Women's	26,064
Horticultural	56,940
Fisheries	42,844
Dairy	5,037

The enlarged scale on which it was found necessary to carry out the works—with a view to complete the original plans proposed, and to meet the great demands of American exhibitors and foreign Governments—has caused a larger expenditure than was at first reckoned on. Various estimates have been made with regard to the total sum which will be required before the opening of the Exhibition to the public. The balance in hand of £410,750 will be exhausted by October 21, the day of dedication ; and it is calculated that, even with the exercise of some economy, a further sum of at least £1,300,000 will be required before the gate-money is available. For this reason, a grant or loan of £1,000,000 was requested from Congress. The Federal Government had participated only so far towards the Exhibition as to appropriate a sum of £80,000 for Government exhibits, £46,000 for the expenses of the National Commission, and £20,600 for medals and diplomas, so that the decision of Congress was awaited with much interest, not only with regard to financial assistance, but as lending substantial proof of the national character of the Exhibition, and disposing of the possible contention that, because the principal funds were raised by Chicago, it was therefore a local enterprise.

After some delay, both branches of the Legislature eventually passed a Bill, on August 5, appropriating 2,500,000 dols. as a gift to the Exposition, in the form of an issue to be made of 5,000,000 half-dollar souvenir coins, and this grant has been accepted by the direction. The souvenir half-dollar will be a legal tender coin, and as evidence at once came forward that they will be sought for at enhanced value, applications having been immediately received for a certain number at a premium, the Directors, on the 12th instant, authorised their disposal at the price of 1 dol. each in sums of 50 or multiples thereof.

Though this grant may thus produce £1,000,000, the Direction are proceeding on the basis of receiving only £500,000 for the coins, and propose issuing bonds to the amount of £1,000,000, bearing 6 per cent., for the purpose of completing the Exhibition and placing the Treasury in possession of ample funds to cover all contingencies until revenues come in. It is not, however, calculated that the whole of this issue will be required ; therefore, only such portion as may be necessary will be floated.

An important condition of the Government grant, which formed part of the Bill, is that the Exhibition shall be closed on Sundays. It is thought that this condition may prove to be somewhat prejudicial to the enterprise, but, unless the question be again raised at the next meeting of Congress, when the compromise of a partial opening of the grounds is hoped for, the decision is final.

The entrance payment is fixed at 50 cents, with a small additional sum for admittance to the Midway Plaisance. For some months past the grounds have been open to visitors at an entrance fee of 25 cents, and on Sundays as many as 20,000 people have visited the buildings in course of construction. The total receipts from this source up to the 11th instant have been £12,383.

Dedication.

The date fixed for the dedication of the Exhibition has been changed from October 12 to October 21, when the buildings will be formally handed over to the nation. The former date was the date on which, according to the old system, Columbus first discovered America, and the latter date corresponds with our present calendar. The programme is not yet finally decided on, but the ceremonies will extend over three days—from October 19 to October 21—the final dedication taking place in the Manufactures and Liberal Arts Building in the presence of the President, and where seats will be provided for the guests who witness the ceremony.

On each of the three nights there will be a pyrotechnic display, which, it is intended,

shall be both magnificent and novel. A striking feature will be the procession of the centuries, consisting of 24 floats, to be drawn by cable through the waters of the grounds, and manned by groups of living figures, designed to represent peace, literature, the various arts, and other subjects illustrative of progress. On the first and second days a military parade and a civic spectacle will take place. It is proposed that 15,000 troops shall assemble, and be quartered in or near the Exhibition buildings. Invitations have been sent to all fraternal, patriotic, industrial, and civic societies in the United States to participate in the civic spectacle. This procession will pass through the principal streets of the city, and will be reviewed, as will also be the troops, by the President, the Members of the Senate and the House of Representatives, the Foreign Representatives, and the Governors of the States.

Proceedings of the Society.

CANTOR LECTURES.

USES OF PETROLEUM IN PRIME MOVERS.

By Professor W. Robinson, M.E.,
Assoc. M.Inst. C.E., University College, Nottingham.

Lecture II.—Delivered March 7th, 1892.

Petroleum Oil Engines.

The task before us to-night is to consider the use of petroleum, at once as fuel and working agent, in the cylinder of the internal combustion engine. This is by far the most important application of petroleum for the production of mechanical energy; and I feel it is almost impossible, in the time at our disposal, to fully discuss all the points I should like to bring before you on this subject. However, I shall touch on some of the more salient points, if you will allow me to deal with them rapidly.

The typical samples of oil most suitable for this purpose are generally known as burning oils, intermediate oils, and, in some cases, even light lubricating oils. Various constants, obtained from experiments on samples of these oils used in oil-engines, are given in Table I. of last lecture, *ante* p. 964.

The wholesale prices of these oils, delivered naked in London or Liverpool—that is, after allowing one penny per gallon for the barrels—are also given in Table I. We can buy American Royal Daylight oil at 4d. per gallon; American Ordinary, 3¾d.; Water White, 5d.; Tea Rose, 4½d.; Russian Ordinary (Russolene), 3½d.; Russian Lustre, 4d.; Broxbourne Lighthouse, 5½d.; Scotch gas-oils, 2½d.; Intermediate oils, and light lubricating oils at 2½d. per gallon. For towns far inland, the cost of carriage must be added; still, these prices do not prohibit the use of the oils in prime motors, although we pay very much less for the same weight of coals in this country.

We have already dealt with the characteristic properties and chief tests of petroleum. The curves plotted from the results of the fractional distillation show at a glance that whereas some of the oils give off only a little vapour slowly, and in gradual stages, throughout a very wide range of temperature, and although other samples do not commence to distil until heated to a higher temperature, yet some of these come off more quickly, and the greater part of an oil like Lighthouse is vaporised at the temperatures reached in our experiments. We must constantly bear in mind that petroleum, and even the refined burning oils, behave in a rather peculiar manner when subjected to heat. At the ordinary atmospheric temperature (60° Fahr.) in the first place, you find evaporation going on imperceptibly from the free surface exposed to the air until a certain fraction is got rid of, and then evaporation practically ceases, unless the oil is greatly agitated or heated.

Further, any one of the refined burning oils appears to consist of a mixture of hydrocarbons of nearly uniformly graduated specific gravity and boiling points, and thus widely varying volatility. It follows, from the nature of petroleum, as shown by experiment, that the

Effects of Heat

upon ordinary kerosene or burning oil, at gradually increasing temperature, may be divided into three distinct stages:—

1st. *Vaporisation*, at a low temperature, when the more volatile portions of the oil-vapours, consisting of the lighter hydrocarbons, evaporate freely.

2nd. *Cracking* takes place as the temperature of the oil is raised, in order to force complete evaporation. Not only do we find oil-vapours driven off, but at the higher temperatures some of the heavier hydro-carbon vapours are "cracked" or split up into various other hydro-carbons, yielding gas, lighter vapour,

and leaving a very slight carbon deposit, so that the greater part of the oil is converted into vapour without producing any troublesome deposit of carbon.

3rd. *Gas-making.*—On still further raising the temperature to a cherry-red heat, as in the ordinary process of oil-gas manufacture, when the oil is dropped into red-hot retorts, or passed in small quantities through highly heated coils exposing sufficient heated surface, the oil is partially or entirely decomposed and converted into real oil-gas: a fixed, permanent gas. At the same time tarry products are formed, which are usually washed out in the process of gas-making, but are troublesome in oil-engines, because these tarry products, and the deposits from them when burned, rapidly clog the valves, passages, and working parts of the engine, and bring it to a standstill.

Now it is found, in practice, that, by regulating the temperature carefully to a nicety below this gas-making stage, the ordinary kerosene oil may be split up or converted into light products and kept in the state of vapour, especially when thoroughly mixed with excess of air, which holds the vapour cloud in suspension. Experience, then, leads to the conclusion that a really commercial and successful oil-engine must use the oil as oil, and not as oil-gas, unless the tarry products are removed by some process of washing, and the oil-gas thus washed, cooled, and cleansed before being admitted into the engine cylinder.

In the next lecture we shall treat of oil-gas and its uses in the ordinary gas-engine. At present, we are dealing with the use of oil itself, and oil vapour, not gas. We should, therefore, note the arrangements, if any, in oil-engines intended to automatically control the temperature of the vaporiser, so that only oil vapour is formed.

Preparation of Charge.

When considering oil-engines, the fact should not be forgotten that we have entirely different conditions to those connected with steam or gas engines, where the working fluid, dry steam or gas, is supplied to the engine ready made; whereas, the oil-engine has to prepare and vaporise the oil for its own use. The steam boiler is relied upon to supply dry steam to the engine at the desired pressure. In the case of the gas-engine, we have simply to turn on the gas cock, and rely upon the gas manufacturer to make gas of such quality as to give equally satisfactory results in the motor cylinder, whether used for a short or longer period. But in the oil-engine we meet with an entirely different state of things, as regards supply of the working agent. The oil must be taken direct from the oil cistern, vaporised, and thoroughly mixed with the right proportions of air, for complete combustion, and passed into the cylinder ready for ignition, at the rate, in some engines, of three or four separate charges per second; so that, unless the arrangement for dealing with the oil is correctly adjusted, and works properly with precision, the tendency to clog in the working organs is very great. The engine then just becomes like a strong looking man with a poor constitution, and suffering from pulmonary troubles: it will run well for a short time, but very soon, getting choked up, refuses to work or run any longer.

Classification of Oil-engines.

Perhaps the action of the different kinds of successful petroleum oil-engines will be best understood from the above, if we classify them all under three distinct types, depending on how the oil is treated in preparing the charge.

First Type, in which the oil is *sprayed*, and heated or otherwise *converted into vapour*, and ultimately mixed with the right proportion of clean air before being admitted into the cylinder, where the charge is compressed and fired, as in the Otto gas engine—example, the Priestman oil-engine.

Second Type, that in which oil, in the liquid state, is injected into a hot cartridge at end of cylinder, where it is vaporised and mixed with the air compressed into this hot combustion-chamber, and fired, as in the Hornsby-Akroyd oil-engine.

Third Type is provided with a *vaporiser* or *gas generator*, such as a heated chamber or a heated coil, to convert a little drop of oil into vapour, or oil-gas and vapour, by means of an oil lamp burner. Then the crude oil-gas and heated products are drawn directly into the cylinder, mixed with the right proportion or slight excess of air, and the charge compressed and fired, as in the Trusty, Capitaine, Crossley, and other oil-engines.

The cycle of operations in the oil-engine cylinder is generally that of Beau de Rochas, the same as in the ordinary "Otto" gas-engine. This cycle works very well, giving more uniform steady running than in the gas-engine.

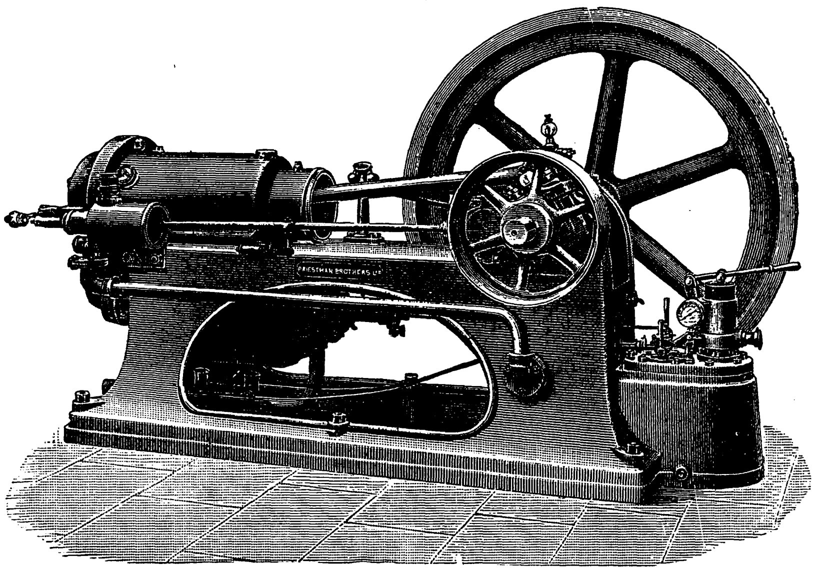
Class I.—Priestman Oil-engine.

The Priestman oil-engine (Fig. 15) is a practical success as a prime mover, and is the most common form of oil-engine employed in this country.

We have the engine here in the room, and in addition, placed on the table before you, the most important parts, namely, oil-tank and pump, spray-maker, vaporiser, heater, and igniter. As pointed out in my last lecture, the oil is forced from the tank by an air-pump, and the oil thus delivered to the spray-maker is controlled by the engine-governor, which allows the oil-jet to pass through a plug into the spraying-nozzle. (Explained by samples on table, showing section, also drawings—Figs. 5 to 9, pp. 971 and 972—in last lecture.) In the spraying-nozzle the oil-jet is broken up into exceedingly fine particles by a current of air, at the same pressure, from the top of the oil-tank. The mixed air and spray-cloud are then heated in the vaporiser by the hot exhaust gases escaping from the cylinder through the jacket around the vaporiser.

During the next suction stroke of the piston, an additional air-supply is drawn in through the spray-maker (Fig. 5, p. 971) by the wing-throttle valve passage, regulated by the governor, so as to form with the oil the right proportions for explosive mixture. This inrush of fresh air carries the charge of oil-vapour (heated spray-cloud) into the engine cylinder.

Fig. 15.



General View of Priestman Oil-engine.

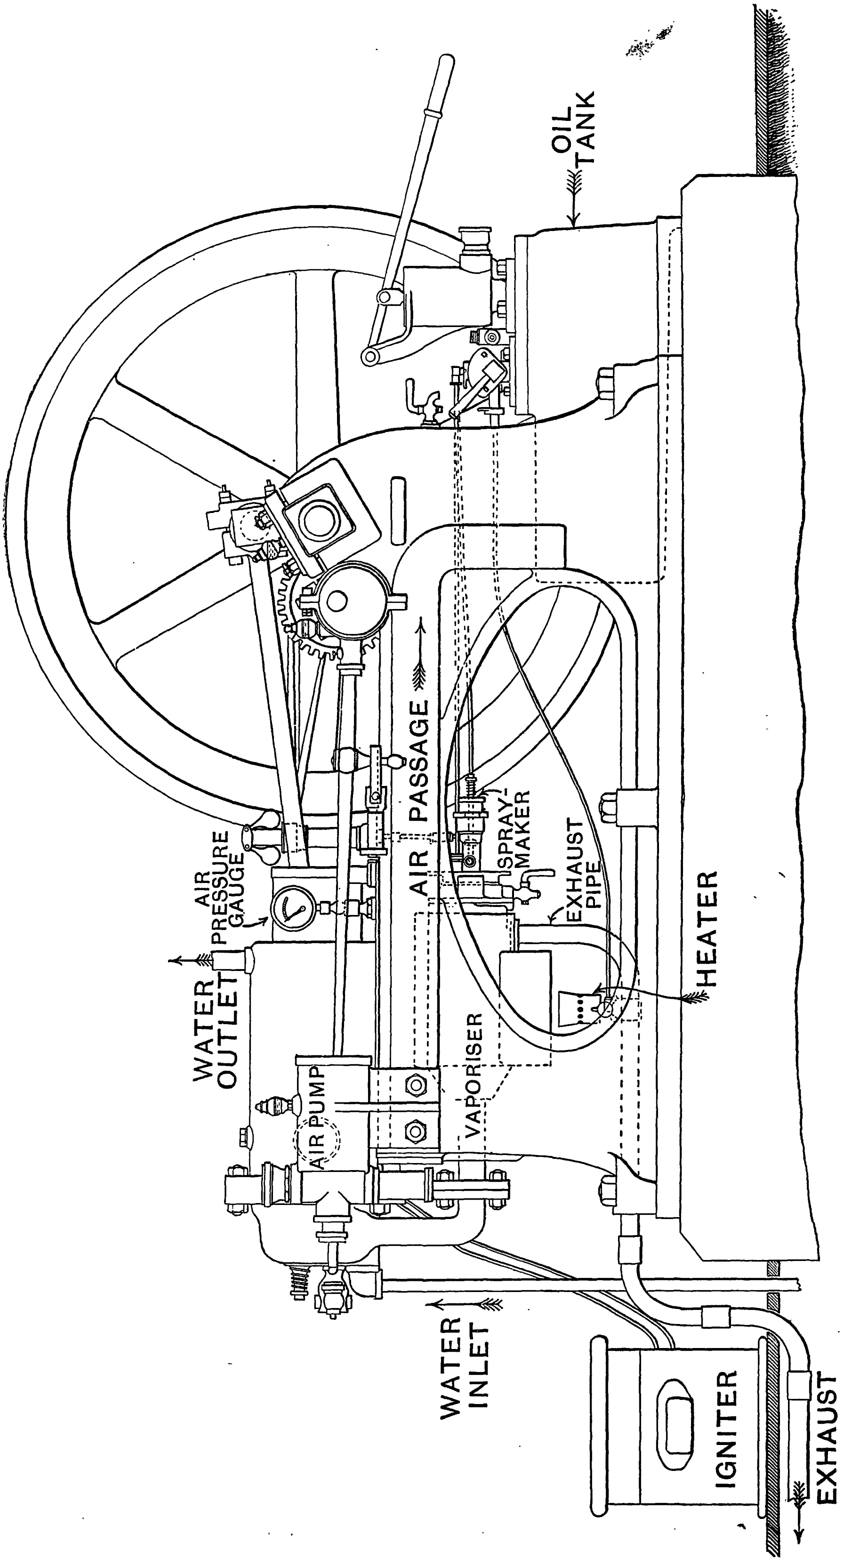
The charge, compressed during return stroke of piston, is fired by the electric spark, expands, doing useful work, and is driven out by the exhaust, the operations in the cylinder being the same as in the Otto gas-engine.

You will perhaps more easily follow this action after examining the engine itself, which we have here in the room, together with the essential parts or vital working organs on the table, explained by the drawings and wall-diagrams, Figs. 15 and 16.

Oil Supply to Engine.

The oil supply requisite for a run of a day or two is contained in an oil tank shown outside the engine-bed, Fig. 16 (p. 987). During a prolonged run this tank may be replenished, if need be, from the large oil supply tank by gravitation, as in Fig. 17 (p. 988), without ever stopping the engine. The air-pipe connecting the two vessels allows the pressure to become the same in both, and the oil flows down because of the "head" or difference of levels between the surfaces.

Fig. 16.



Essential Parts of Priestman Oil-engine.

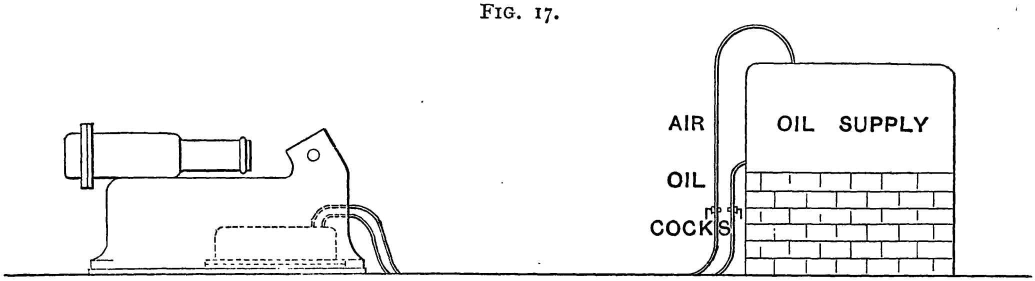
In places where this is inconvenient, the hand-pump (Fig. 18) is used to force the oil up into the small tank at the engine.

A protected glass gauge shows the oil-level in the tank.

Spray-making.

When *starting the engine*, the hand-pump (Fig. 16) forces air into the tank and delivers the oil to starting lamp or heater for vaporiser.

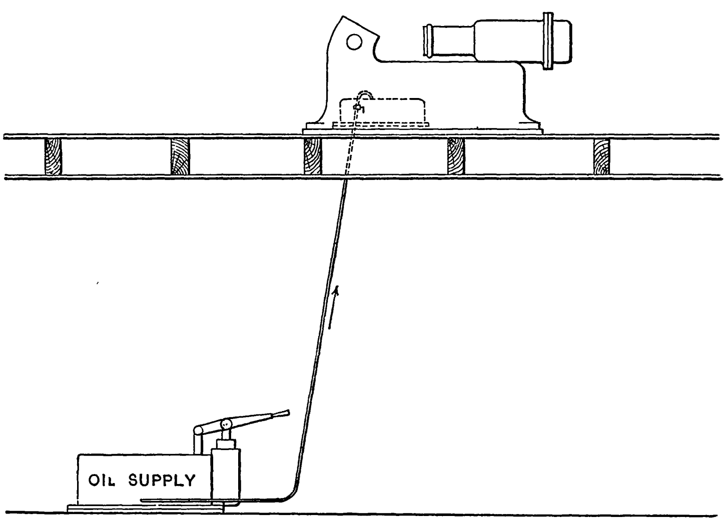
Fig. 17.



Priestman's Oil Supply by Gravitation.

Afterwards, when engine is running, the air-pressure is maintained by the small pump at the side of the cylinder driven by the eccentric and side-shaft. An escape valve on the oil-tank keeps the air-pressure constant, as shown by the gauge. This pressure is regulated for the different kinds of oil and size of engine, and is usually from about 4 lb. in small engines, to 15 lb. per square inch above atmospheric pressure in larger sizes. The air is drawn into the pump through fine gauze and a filter of cotton-wool, to clean and rid it of dust, dirt, grit, and even moisture, so that thoroughly clean dry air is used to spray the oil, otherwise the fine passages in the spraying-nozzle would be blocked or choked

Fig. 18.



Priestman's Oil Supply by Pump.

up. In fact, all the air which enters the spray-maker and cylinder is cleaned in this way.

The auxiliary air supply to the spray-maker is shut off until the engine is started, by turning a little shutter fixed on the end of the throttle-valve passage.

The oil-tank is provided with a six-way cock, arranged so that when the handle is upright the cock is closed; turned to the left,

supplies the starting lamp with oil and air; and with the handle to the right, the cock allows the oil and air to be delivered to the spray-maker in ordinary running.

In starting the engine the vaporiser is heated up by the spray-burner placed under it, and supplied by oil and air through six-way cock from the oil-tank, in which pressure, 4 to 15 lb. per square inch, is got up by hand pump depending on size of engine. You see this clear, bright, powerful flame without any smoke deposit (experiment shown) heats up the vaporiser in from 5 to 15 minutes. Then the oil and air is forced into the vaporiser through the spray-maker, and the charge is ready to be drawn into the engine cylinder, by giving the fly-wheel a few turns.

Regulation of Charge.

As explained in my last lecture, the proper proportion of oil and air is practically determined once for all when adjusting the spray-maker. The exact amount of oil passing through the nozzle is caught in this little bottle, which measures the number of drops per minute, while the air-pressure in the oil-tank is kept constant. Then the amount of air is adjusted by the wing throttle-valve, on the same spindle, to suit the oil admitted until the best indicator diagram is obtained, and when permanently adjusted the governor automatically regulates the strength of charges, to give the power required at any time and maintain the normal speed.

As you have already seen (Figs. 5 and 8, p. 971), the oil-valve is of the plug type, and the hole through which the liquid passes is cut into a **V**-shaped notch. The larger end of notch is covered, and the oil enters by the sharp end, thus allowing a wide range of regulation by simply turning the plug. Even when the engine is running light, there is always a very tiny corner of the apex of the **V**-notch open, to admit a little oil and keep the engine going. There is no complete cut-off of the oil at any time. The wing throttle-valve is fitted to a prolongation of this plug, so that both valves move together. No matter how the engine is working—with half load, full load, or running light—the governor maintains the normal speed, by admitting the charge of varying strength, but always made up of the right proportion of oil and air to form an explosive mixture.

Vaporisation.

You observe this cold spray cloud is sufficiently mixed with air to burn with a clear flame. (Experiment shown.) Subsequent heating of the finely-divided spray in the vaporiser is necessary, to thoroughly vaporise the oil before allowing the mixture into the engine cylinder.

Some of the heat from the burned products carried away in the exhaust is saved, and utilised to heat the incoming charge. About 10 or 12 per cent. of the total heat of combustion of the oil may thus be restored and utilised or regenerated in the vaporiser. The temperature of the charge on entering the cylinder varies from 170° Fahr., in a one horse-power engine, to about 258° or 300° Fahr. in a five horse-power, so that the temperature is kept well within the vaporising stage.

However, in order to ensure complete combustion of the oil, it would appear that, in some cases, fully 2·5 times more air is admitted than that which would furnish the exact amount of oxygen necessary for complete combustion, according to the chemical analysis of the oil.

Firing of Charge.

The explosive charge, prepared in this way, is drawn into the cylinder by the piston during its outward suction-stroke, compressed during the return-stroke, and fired by an electric spark between two insulated platinum points, in a brass plug screwed into the clearance space at end of the cylinder. The platinum wires pass through porcelain plugs fixed with Plaster of Paris in the brass plug, and the terminals are connected by two wires to a small induction-coil, excited by a bichromate battery contained in the "igniter" box shown (Fig. 16, p. 987) at back of engine. The battery circuit is completed at the proper moment by a knob or finger on the eccentric rod making contact between two brass springs in the shape of a fork. This fork can be adjusted and moved back by means of a screw, to give late ignition when starting.

Unfortunately, this mode of ignition was a failure in the early Lenoir engine, because of short-circuiting by water-vapour, which undoubtedly condensed on the platinum points, and prevented the spark playing across between them.

However, lest you should think that miss-fires may be caused in the same manner by deposit of oil or soot, I wish to prove, by a simple experiment, that oil-vapour acts very differently from water-vapour between the electrodes.

I hold in my hand an old ignition plug (Priestman's) which has been covered with a deposit of soot. I will put more soot on by means of this oil flame. Now observe the spark from this little induction coil still passes between the platinum points, and burns away the soot deposited on them. (Experiment shown.) Again, I shall put some oil between these dirty points, so as to bridge them across with liquid oil, which also covers the porcelain plugs. Still the spark passes, and burns away the oil (experiment shown), so that you see for yourselves it is not at all necessary to have these platinum points perfectly clean in order that the spark may play between them. Why, one of the best electric sparks we have is in the arc lamp, where the spark plays between two sticks of carbon, and the temperature is high enough to volatilise the carbon. Moreover, the electric arc may be made to pass between two carbon sticks, completely immersed in ordinary paraffin oil. Suppose there is a little deposit on these platinum points, even if this ignition plug is covered with soot, and then fixed in the engine cylinder, you will find that, after a few explosions, under ordinary working conditions the deposit is cleared away by the explosions in the cylinder, and the plug is cleaned, while the electric spark is as good as ever.

As a matter of fact, the conditions for ignition are different in the oil-engine and gas-engine. Oil is a very good insulator, consequently any slight deposit of oil between the platinum points only serves to insulate them, does no harm, and is burned off. On the other hand, water is a conductor of electricity, so that a film of water on the ignition plug short-circuits the platinum points, and makes it possible for the electric current to flow continually, along the path of smaller resistance provided by the water, instead of jumping across between the electrodes.

However, by taking in clean, dry air through the cotton wool, and clearing away any deposit of aqueous vapour formed when the engine is standing over night, so that every part is dry, the spark will act with certainty. By means, then, of this sure and powerful mode of ignition, the compressed charge is fired at the end of the cylinder, and the burning expanding gases drive the piston forward.

The charge of vapour and air is drawn from the vaporiser into the cylinder through the upper valve at the back of the cylinder, opened automatically by the suction of the piston. The lower valve for the exhaust is opened by an eccentric on a shaft geared to the half speed of crank-shaft.

The functions of the eccentric rod are threefold:—1st, as piston-rod to the little air-pump to compress air, along the air-passage into the oil-tank, and this air-pressure forces oil and air into the spray-maker; 2nd, the prolongation of the rod opens the exhaust valve every second revolution, at the right time, and allows the burnt products to escape around the vaporiser when driven out by the engine-piston; 3rd, to fire the charge, a knob or contact finger, fixed on the rod near the eccentric end, is brought between two springs, and thus completes the battery circuit at the right moment to excite the induction coil, and make the electric spark play between the platinum points inside the cylinder. As already pointed out, these contact springs can be screwed back and adjusted to make the time of explosion late, or just immediately after the piston passes the dead point.

This late ignition is a special feature in the Simplex, engine of Messrs. Delamare, Deboutteville and Malandin, of Rouen. The ignition takes place when the piston has travelled some distance on its out-stroke after compression; and it is found that more work is done with comparatively late ignition, and results in much steadier running, giving less shock to the bearings, whilst the pressure is better sustained throughout the working stroke.

The engine cylinder is cooled by a water-jacket, the water inlet being below the cylinder, and the outlet above, as shown in Fig. 16, p. 987.

You will readily understand that in the construction of oil-engines, the great point is to get economy of oil, and the best mechanical results, without clogging of the working parts, so that the engine may run steadily, without requiring attention or frequent cleaning and repairs. In the Priestman engine, clogging is prevented by thoroughly mixing the oil vapour with a large proportion of clean atmospheric air, so as always to form an explosive mixture which gives complete combustion and a clean exhaust under ordinary working conditions.

Cylinder Lubrication.

It must be pointed out, as a peculiar feature in the working of the engine, that, during the compression of the charge before ignition, a small portion of the oil vapour, coming in contact with the cylinder walls, condenses on

them, and never gets burned. Still, this condensed oil forms, in its heated state, an excellent lubricant for the piston and cylinder surface, thereby dispensing with the need of a more costly oil, and regulating the lubrication without any attention being required. The perfect state of the piston surface, after being months at work, without any other lubrication, affords ample evidence of the advantage gained by this self-lubrication with a minimum of trouble and expense.

Compression of Charge.

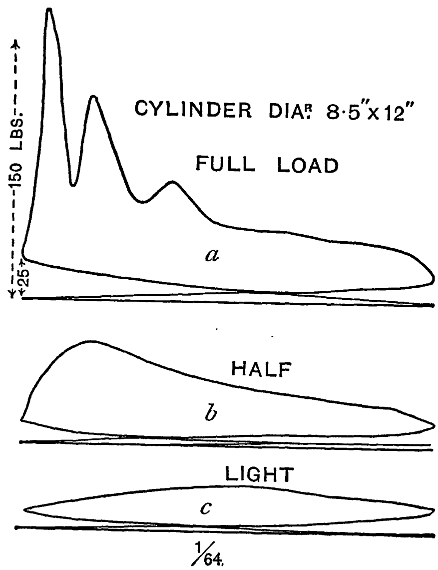
The compression of the charge before ignition only to about 25 or 30 lb. per square inch above atmospheric pressure, is kept low, for fear of much condensation as well as to give smooth running to the engine. In the gas-engine we know that compression of the charge before ignition is essential to high efficiency, and similar considerations lead one to expect the same to hold true for oil-engines. In experiments made on the five horse-power engine, it was thought advisable to try an extra supply of fresh cold air, admitted directly into the end cylinder by a separate pipe, and mix this extra air supply with the previous charge, after leaving the vaporiser. Obviously, very much higher compression than usual, greater power or higher efficiency was obtained; the oil consumption came out ·85 pint, instead of ·93 pint (formerly) per hour per brake horse-power. But then, on the other hand, the temperature of the cylinder became too high for ordinary everyday working, and experience points to a certain limit of temperature that may be reached for economy. For the same reason it is thought advisable to utilise only a small portion of the available heat of the exhaust products, to heat up the fresh incoming charge of sprayed-oil and air. The temperature of the charge on entering the cylinder was 258° to 300° Fahr., in a five horse-power engine, and the temperature of the exhaust gases after leaving the jacket vaporiser was in some instances above 600° Fahr. About 10 per cent. of the total heat of combustion of the oil is thus regenerated in the vaporiser.

Indicator Diagrams.

Fig. 17 shows (nearly half-size) typical samples of indicator diagrams of this engine, for (*a*) full load, (*b*) half load, and (*c*) running light.

The wavy irregularities in line for expansion are perhaps entirely due to the vibration of the indicator spring, which was not quite stiff enough (only $\frac{1}{64}$) to withstand the sudden blow of the explosion. The greatest height represents about 150 lb. per square inch, but the upper part is doubtless due to the vibration, and a stiffer spring would give the mean explosive pressure, about 120 or 130 lb. per square inch. The method of governing is clearly shown. With full load the compression is about 25 lb. per square inch. At half load the governor turns the oil plug, and cuts off part of the oil and air, so that the charge is smaller, and the compression pressure in the same clearance space is reduced by one-half. Consequently, although the charge is ignited at the same moment, the combustion proceeds more slowly, yet with considerable force, and the highest pressure is not reached until the piston has travelled forward a considerable distance. The work done by the gases in the cylinder is made to fit the load on the engine. Finally, when the engine is running light, there is still less oil and air admitted, the compression is diminished, and the explosion is very gradual, giving greatest pressure about mid-stroke.

Fig. 17.



Indicator Diagrams from Priestman Oil-engine.

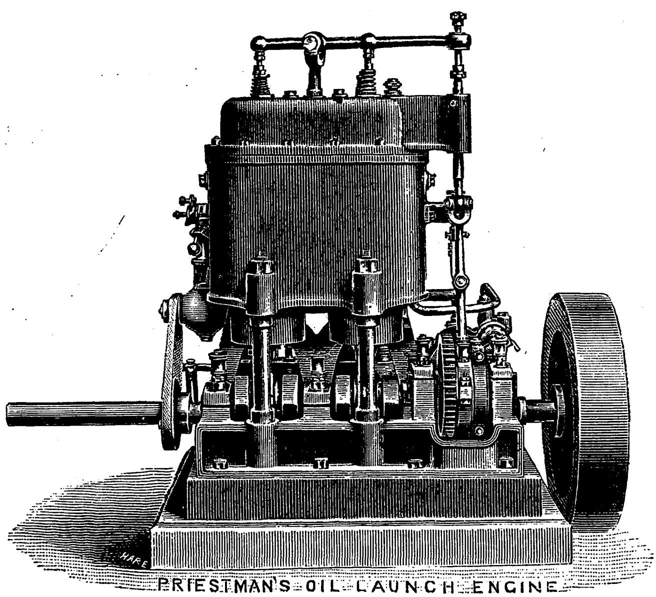
Priestman Engine, Marine Type.

The double-cylinder vertical oil-engine, Fig. 18, is specially designed to run at high speed for marine work, such as driving canal barges and launches. The 5 horse-

power engine has 7-inch cylinders, 7-inch stroke, speed 250 revolutions per minute, and gives one explosion, or working stroke, every revolution of the fly-wheel or heavy disc. The 10 nominal horse-power marine type oil-engine has two cylinders, each 9 inches in diameter by 9 inches stroke, speed 240 revolutions per minute, propelling the boat about nine miles an hour.

The action is similar to horizontal type, the oil being sprayed by compressed air, and heated in a vaporiser by the exhaust gases. The valve gear is very simple. The inlet valves on top of cylinder act automatically. An eccentric on the countershaft, geared to half-speed of crank shaft, drives one vertical eccentric rod, which is timed to open the exhaust valves of both cylinders, against stiff spiral springs. The air-pump which forces oil out of the tank into spray-maker, and the jacket-water circulating pump, are driven by an eccentric on the same countershaft. The spray-maker is of the ordinary type, and the vaporiser is supported from the cylinders. The governor which regulates the supply of oil and air to the spray-maker is driven by belt from crank shaft. The exhaust is carried out at the stern, below water line, or sometimes dis-

FIG. 18.



MARINE TYPE.

charged up a vertical pipe or chimney. Ignition is by the electric spark, and the contact springs can be adjusted to make explosions late when starting. Ordinary burning lamp-oil is used, and the supply for running the boat a week or two can be stored in a tank in the bow, and pumped into the engine oil-tank when required.

The engine runs in one direction only, and a friction clutch is coupled to the main driving shaft for reversing the propeller. A single hand-wheel operates this reversing gear to drive the propeller ahead, astern, or allow the engine to run detached from the propeller. In the latter case, when the boat is stopped for only a short time, the engine is kept running light, controlled by the governor. The boat can be easily handled, and quickly propelled in any direction at will. The engine is well suited for the propulsion of barges and vessels.

CLASS II.—HORNSBY-AKROYD OIL-ENGINE.

The next, and perhaps simplest, type of oil-engine is that in which the oil is injected directly as oil into a hot cartridge, which acts at once as vaporiser and combustion chamber, opening into the engine cylinder. Heavy intermediate oils of specific gravity ·853 can be dealt with as well as ordinary burning oils. One engine of this type is the invention of Mr. H. Akroyd Stuart, of Bletchley, and is

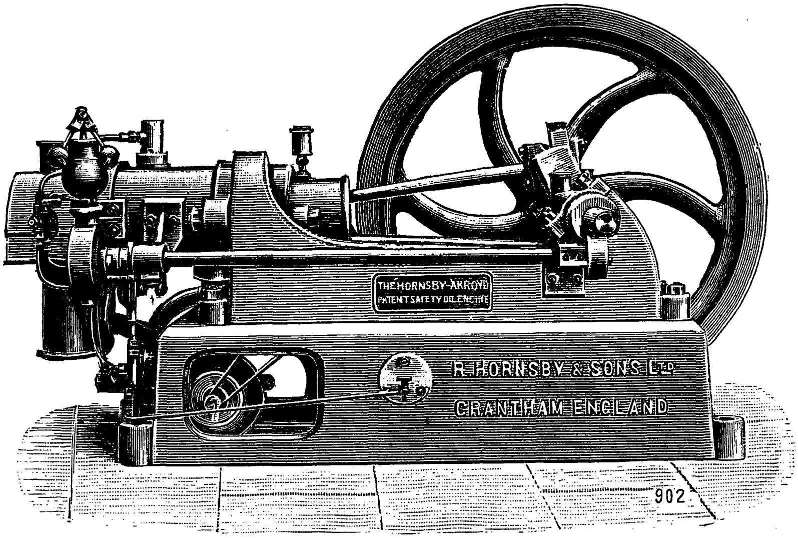
made by Messrs. Hornsby and Sons, Grantham.

The novel feature of this engine is, that the ordinary gear for firing the charge by heated tube, flame, or electric spark, is dispensed with altogether. The heavy oil is injected into the red-hot vaporiser or cartridge, where it is converted into vapour, mixed with air and fired by compression. The Hornsby-Akroyd oil-engine (Fig. 19) is the "Akroyd" engine I described in this room last year, with some modifications of detail. The cycle is the same as in the Otto gas-engine. The essential parts of the engine are shown in longitudinal section and end view in Figs. 20 and 21, pp. 994 and 995.

The vaporiser, or cartridge, C, is of cast-iron, provided with radial ribs to offer a large heating surface to the oil, and communicates directly with the cylinder, A, by the throat or passage shown in Fig. 20. An air-jacket protects the vaporiser from draughts, and regulates its temperature.

The self-acting air inlet valve, D, and the exhaust valve, E, are contained in a box under the cylinder. W is the water jacket around the cylinder. The starting lamp or burner, B L, is filled with oil up to the level of the fan-pipe inlet. The small fan, F, driven by hand, blows air on the top of the oil, and urges a strong clear flame against the vaporiser, and heats it sufficiently in about five minutes.

FIG. 19.



HORNSBY-AKROYD OIL-ENGINE.

The oil-tank is in the foundation, and the charge of oil is forced by means of a pump to the valve-box, V (Fig. 21, p. 995), attached to the vaporiser.

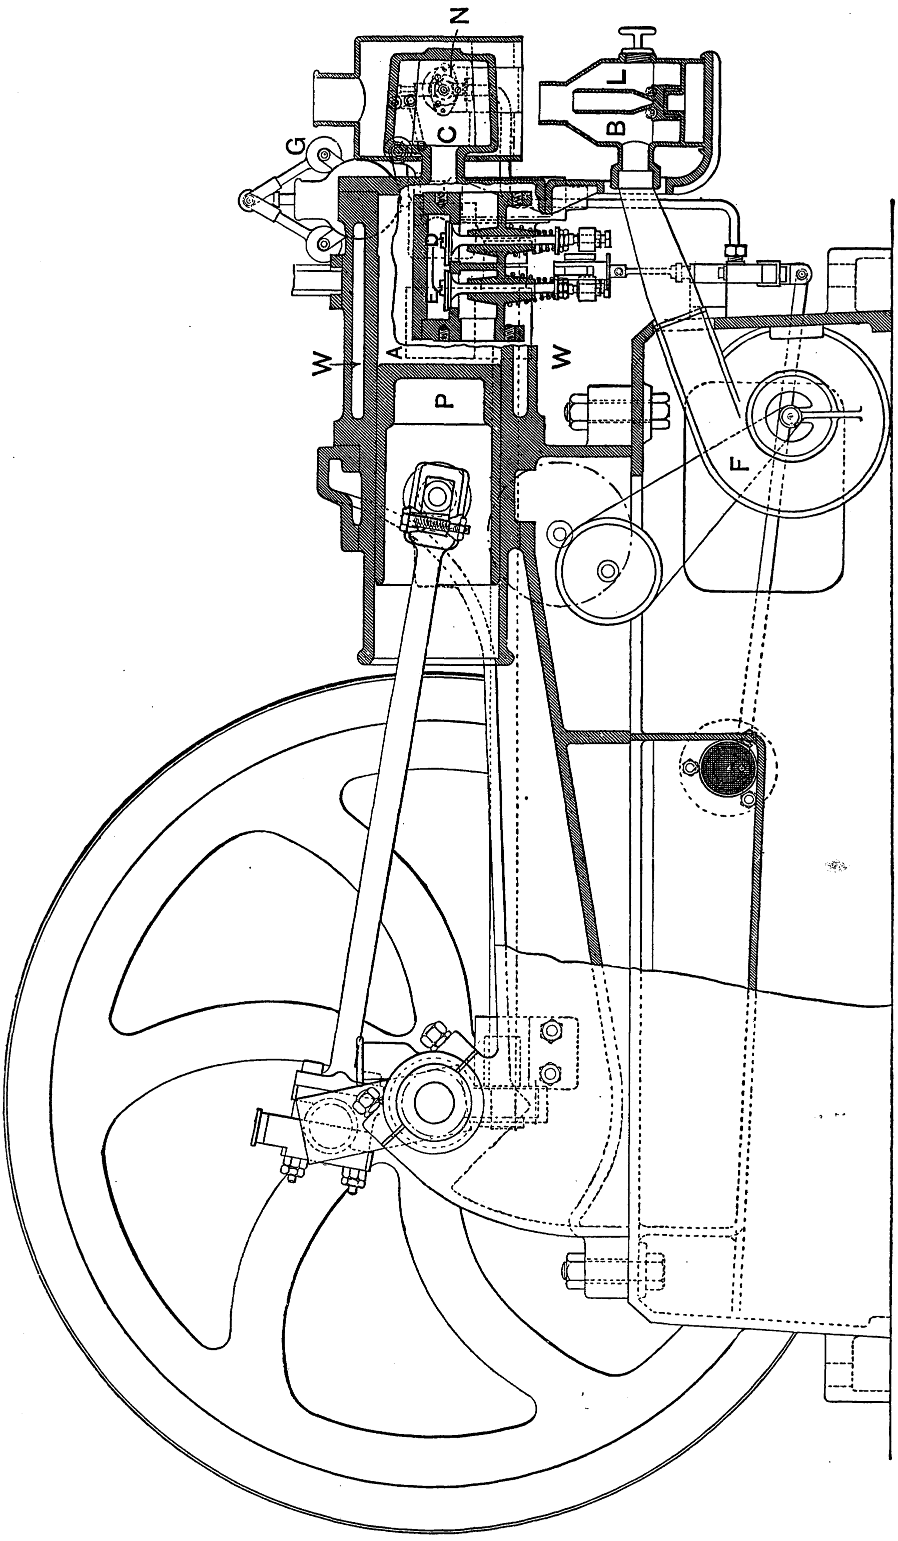
This valve-box contains a horizontal check valve, and a small over-flow or by-pass valve, opened by the governor when the engine is running too fast, allows the surplus oil to flow back to the tank, so that the oil pump is always working, and thus kept in good order.

The valve-box is completely jacketted with water, to keep the oil cool until it enters the vaporiser.

A small Porter governor, G, directly regulates the overflow valve and the inlet valve near the cylinder, and so completely controls and maintains the normal speed at about 200 or 220 revolutions per minute.

The charge of oil is injected by the pump into the vaporiser during the time the air is being drawn in by the piston in its suction stroke. The oil is thus highly heated, and has time to be all thoroughly converted into vapour and mixed with the air during the return stroke, and the explosive mixture so formed is fired by compression inside the hot cartridge. The piston is rapidly driven forward by the burning and expanding gases, giving complete combustion of the charge, so that the exhaust is clean and clear of smoke in ordinary working.

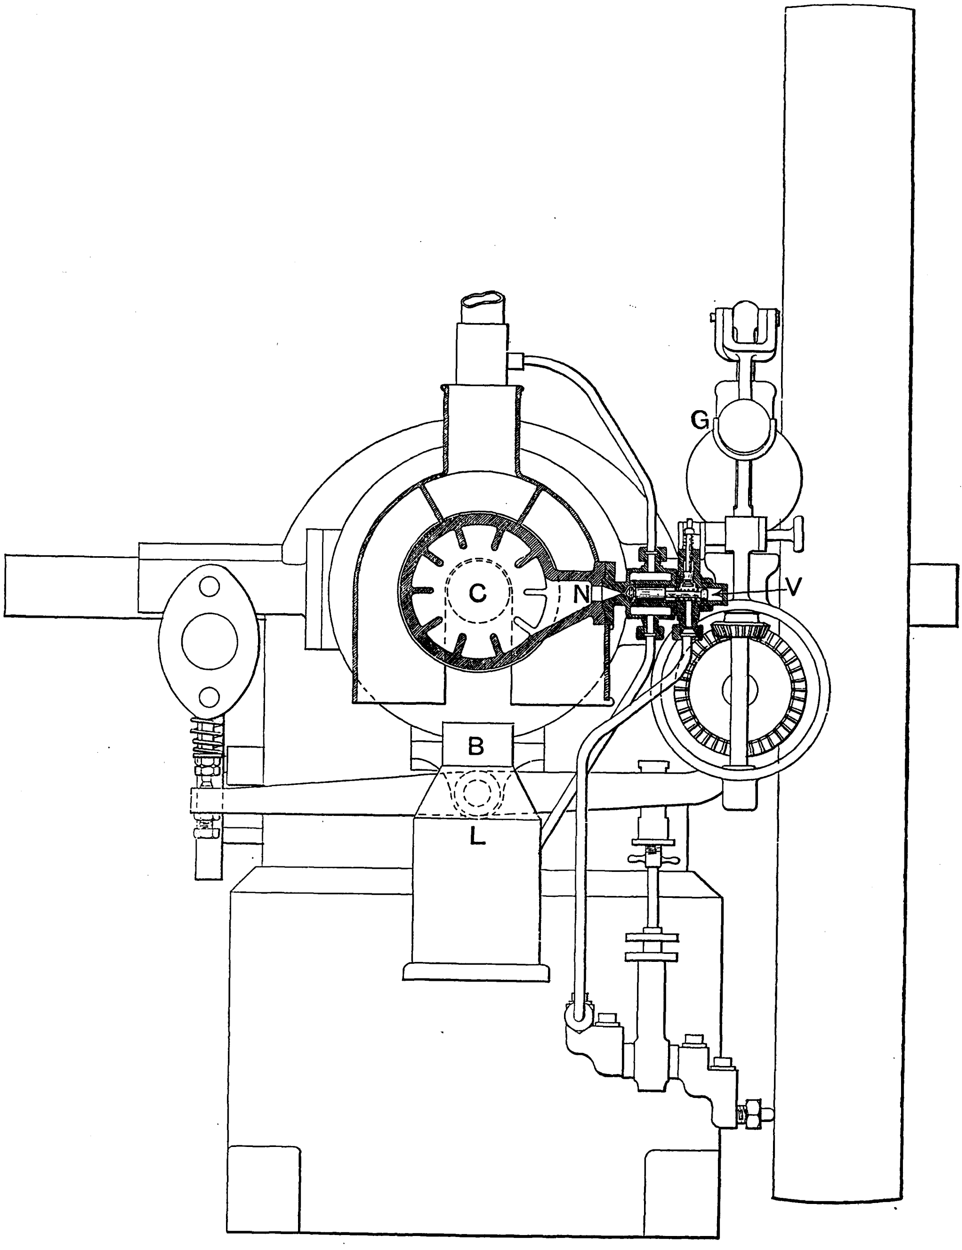
Fig. 20.



Hornsby-Akroyd Oil-engine.—Longitudinal Section.

The indicator diagrams (Fig. 22, *a*, *b*, p. 996), and the full-size card (Fig. 22, *c*) show the high degree of compression which causes the ignition of the charge. The proportion of the volume of vaporiser, including the cartridge and clearance space, to that of the cylinder, in order to ensure rapid and complete combustion, are obtained by experience.

FIG. 21.



HORNSBY-AKROYD OIL-ENGINE.—END VIEW.

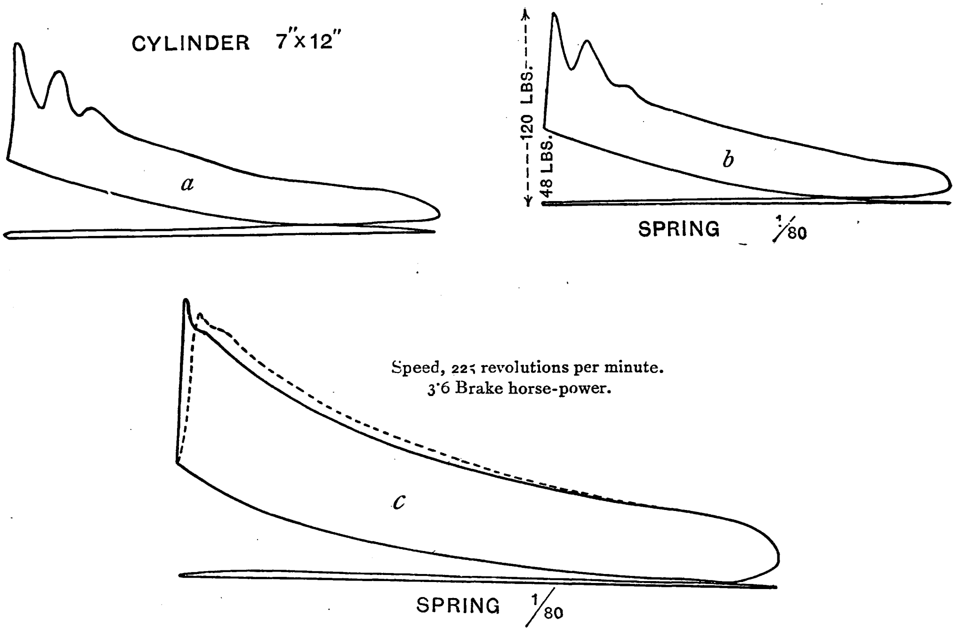
Since there is no condensation of oil, the cylinder requires lubrication, as in ordinary gas-engines.

The cheap intermediate oil used as fuel has a specific gravity of ·853, and flashing point about 225° Fahr. This oil costs 3½d. per gallon in Liverpool, and the average consumption in the engine, under ordinary work-

ing conditions, is about one pint per indicated horse-power per hour, that comes to less than one halfpenny* per hour per horse-power. This cost of fuel for working compares very favourably with that of any other prime motor.

Portable engines of this type are also made with water tank and cooling tubes self-contained.

FIG. 22.



INDICATOR DIAGRAMS—HORNSBY-AKROYD ENGINE.

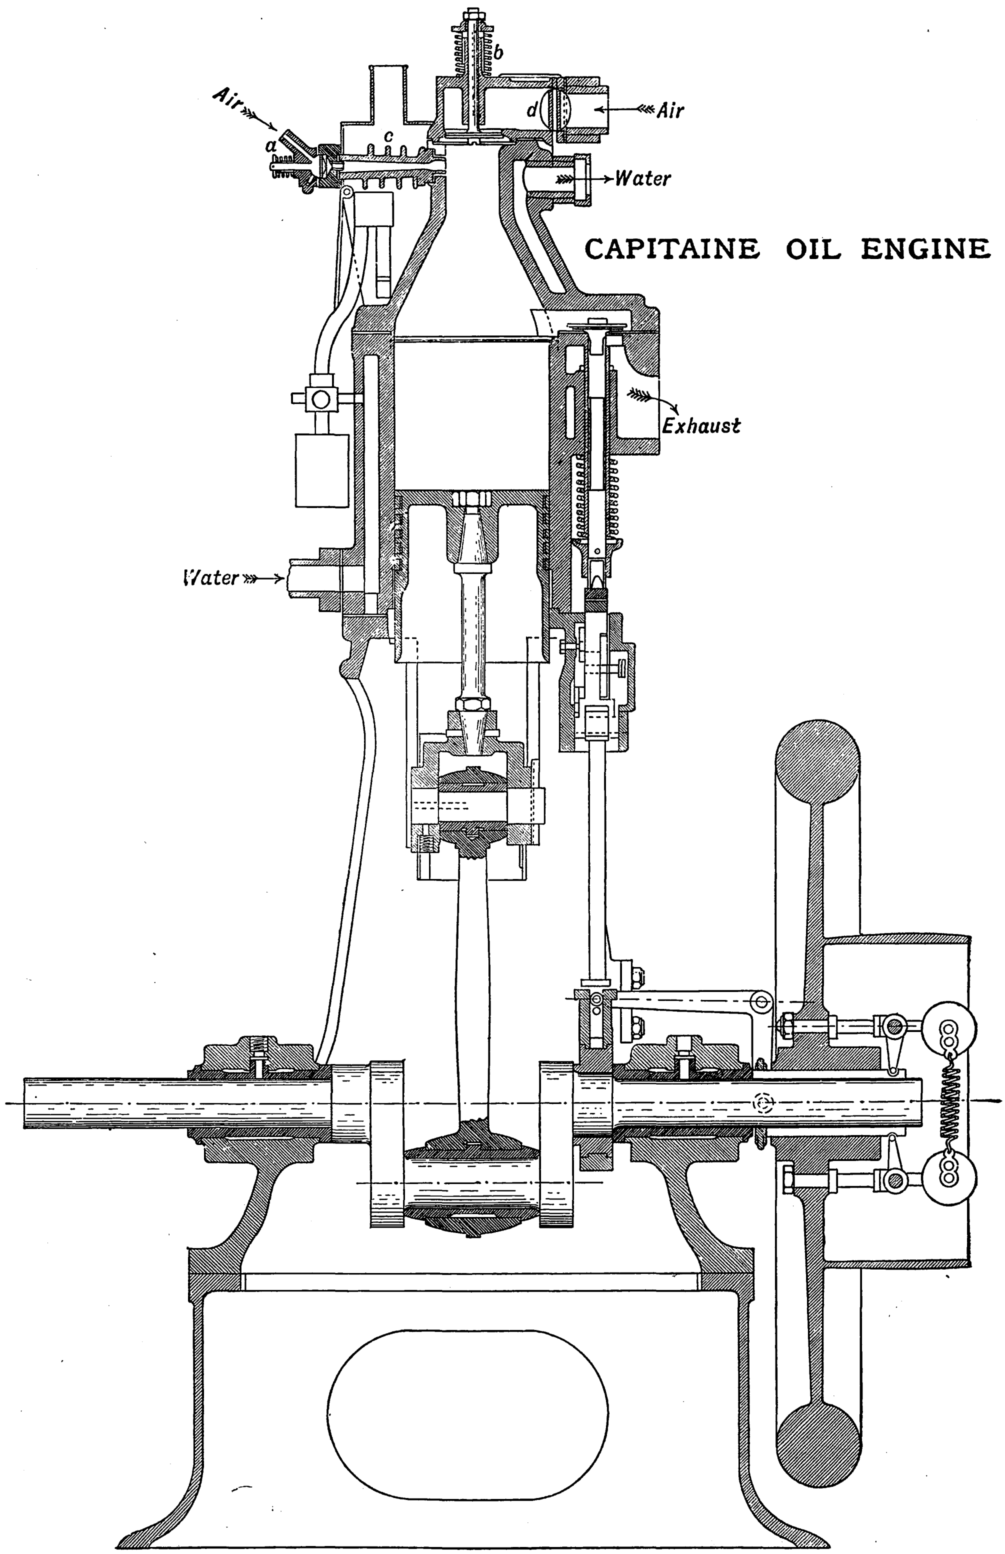
CLASS III.—CAPITAINE OIL-ENGINE.

In the third class of oil engine we find a retort, coil of tubing, or other vaporiser, in which the oil is heated, and converted partially into oil-gas and vapour, by a lamp or other burner. Such a petroleum oil-engine is simply a gas-engine which produces its own oil-gas from the liquid petroleum, overlooking the tarry products, which, sooner or later, make their presence felt, by clogging some of the working parts which need cleaning.

In this case, the vaporiser is really a gas generator.

An example of this type of engine is afforded by the Capitaine Oil-engine, of which we have an actual sample here in the room before us. Fig. 23 (p. 997) shows a sectional elevation of the Capitaine vertical high-speed oil-engine. The truncated piston is connected with a cross-head, which slides in a guide. The top of the cylinder forms the combustion chamber. A small pump supplies oil to the non-return valve passage, *a*, at the top of engine. The motor piston, in its down stroke, opens this valve, sucks the charge of oil, in the form of spray, with a little air, into the vaporiser, *c*. This retort, *c*, is a cast-iron tube flattened egg-shape, with flanges or ribs, to increase heating surface, and is kept at a cherry-red heat by an ingenious lamp, fed by an independent supply of oil from a little tank placed 3 or 5 feet above it. The oil flows by gravitation into this lamp, and ascends to the bent part of the tube, which is heated when starting. Here the oil is vaporised, escapes from below through a small hole, $\frac{1}{100}$th part of an inch in diameter, in the burner cone, and, playing against a piece of incandescent metal, is ignited, and divided in such a way that a most effective blue flame heats the vaporiser retort above the lamp. Consequently, the charge of oil (about ·016 cubic inch in a 4 horse-power engine) sprayed into this retort, kept at a cherry-red heat, is instantaneously decomposed, and converted into a fixed gas and some tarry products. The air enters by the throttle-valve, *d*, and the air-inlet valve, *b*, opened automati-

CAPITAINE OIL ENGINE



cally by suction during downstroke of piston, and the tension of spring on valve-spindle is regulated by hand to admit the exact quantity of air for complete combustion under normal working conditions. In this manner, the air throttle-valve and oil pump may be adjusted, to admit the desired quantity of air and oil, while the engine is in motion. The oil supply is cut off entirely by the engine when governing.

In the engine placed here before you there is no ignition tube; the explosive charge is fired in the vaporiser.

The Capitaine oil-engine also works on the common Beau de Rochas cycle, the same as the Otto gas-engine.

The action of the engine is as follows :—

Before the downstroke of the piston the exhaust valve is closed and the oil pump has supplied the charge of oil to the valve passage, *a*. As the piston moves downward, air is drawn in at *a*, and sprays the charge of oil into the vaporiser, *c*, where it is gasified at cherry-red heat, and is carried forward into the cylinder by the continuous current of incoming air. Air is admitted, during the whole period of the downstroke, both through the top admission valve, *b*, and through the air tube of the spraying valve, *a*. In this way the hydro-carbon gas and vapour will be drawn to the bottom of the cylinder next the piston, and at the end of the down-stroke there will be pure air at the top of the cylinder.

The piston during its upstroke compresses the gas and air into the clearance space and vaporiser, *c*, which is kept red-hot by the outside lamp. As the piston turns the dead-point the compression and contact with the cherry-red vaporiser ignites the charge and the expanding gases drive down the piston.

On the next upstroke the exhaust valve is lifted, the products driven out.

The speed of the small engine of 1 horse-power is 400 revolutions per minute, and that of the 4 horse-power nominal about 300 revolutions per minute.

The mechanical arrangements in this engine are decidedly ingenious. The exhaust valve-spindle and petroleum pump rod are operated by a bell crank lever with three arms, worked by a swinging arm and eccentric rod from the crank-shaft. While the engine is controlled by the governor it does not take in any oil, and all the valves are motionless. The two governor balls, Fig. 23 (p. 997), cast with bell-crank levers, are connected together by a pair of spiral springs and placed within the pulley on the fly-wheel, and rotate with it. When the speed increases, the balls fly apart, move a sliding collar on the crank shaft by means of two rods reaching through the boss of the fly-wheel. The sliding collar moves a bell-crank lever, which pulls down the vertical rod, and its detent on the upper end thus engages an arm on the bell-crank lever, and holds it so as to keep the exhaust valve open and the oil-pump at rest. In fact, while governing, all the valves are quite motionless, no oil is pumped into the cylinder, and the exhaust valve remains open, thus reducing friction, and wear and tear, the piston acting as scavenger, driving all the burnt products into the exhaust box.

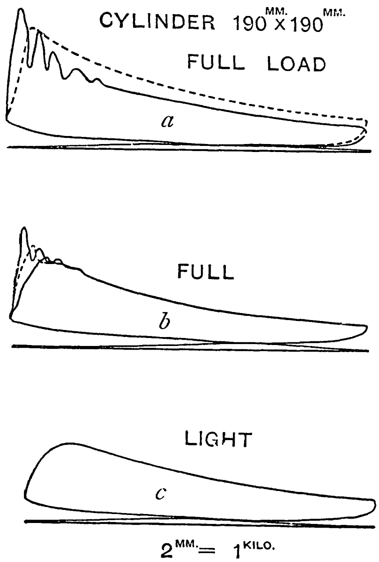
The engine is compact, and occupies little floor space.

However, in my opinion, the method of dealing with the oil is not so satisfactory. The vaporiser, *c*, at a cherry-red heat, converts the oil into real oil-gas, so that there must be tarry products formed which, when burned, leave deposits of soot and retort-carbon in the interior of the engine, clogging the valves. Therefore, inasmuch as cleanliness is essential in every gas and oil-engine, it is absolutely necessary to remove the deposits regularly, at least once a fortnight, or, still better, once a week, for economic working. This is the great trouble in the practical working of such oil-engines that use the oil as oil-gas and not as oil-vapour. Thus the gun-metal tube (inside diameter $\frac{5}{16}$ inch) between the spraying valve, *a*, Fig. 23, and the gas generator, all require cleaning, as there is a deposit of carbon caused by the sudden gasifying of the oil. In the gas generator this is of a soft, sooty nature, but around the tube and the valve it becomes hard. The combustion leaves a deposit of carbon and soot in the compression chamber and exhaust valve. The exhaust box is fitted with a tap-cock, so that the liquid residue, of a light, tarry nature, can be drawn off when necessary.

Fig. 24 (p. 999) shows the indicator diagrams taken from the Capitaine oil-engine, 4 horse-power nominal, with cylinder of diameter 7·5 inches, by 7·5 inches stroke. The results of a trial with this engine, using petroleum of specific gravity ·850, are given as follows:— Compression before ignition, 30 lbs. per square inch; mean effective pressure, 74 lbs. per square inch; speed, 250 revolutions per minute; indicated horse-power, 7·05; brake horse-power, 5·64; consumption per hour per brake horse-power, 0·84 pints of petroleum.

Experience with this engine in practical every-day working, under ordinary conditions and without skilled attention, can alone decide

FIG. 24.



INDICATOR DIAGRAMS, CAPITAINE OIL-ENGINE.

in how far the troubles likely to be caused by the deposits from tarry products, have been overcome.

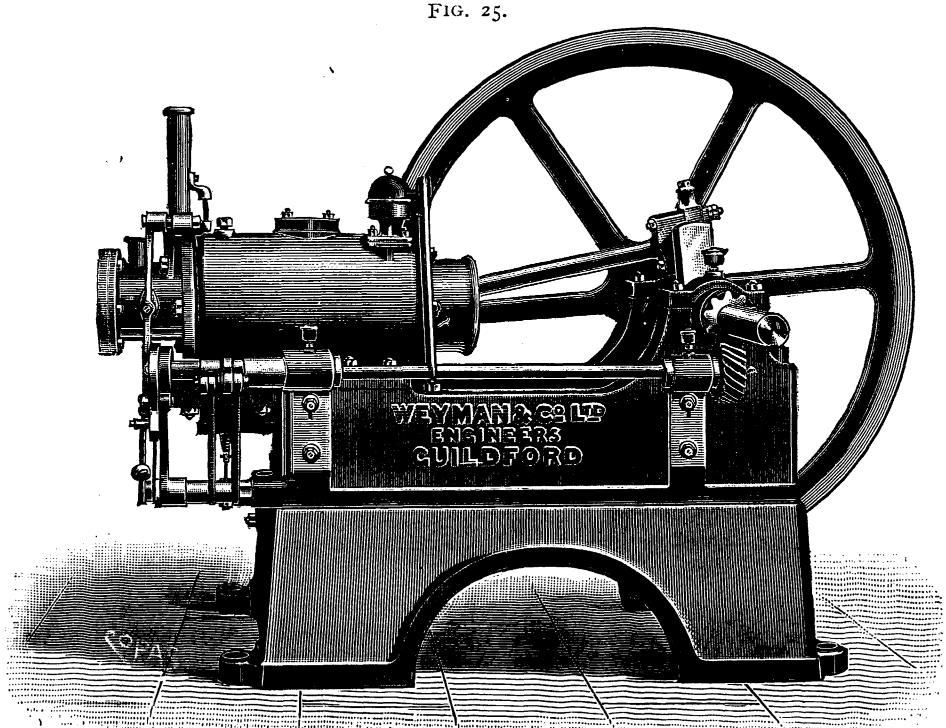
TRUSTY OIL-ENGINE.

As another example of the third class of oil-engine, we may take the Knight engine, as modified by Messrs. Weyman and Co., of Guildford, and now called the Trusty oil-engine (Fig. 25).

In this engine there is no spray-making arrangement whatever. The oil is vaporised or gasified before being admitted into the combustion chamber, where it is mixed with air to make up the explosive charges. The extension at the back of the cylinder (Fig. 25) forms a compression and combustion chamber inside, and the outside annular space or jacket forms the vaporiser, heated by an oil lamp when starting, and afterwards by the explosion of the charges in the cylinder and combustion chamber.

The oil is pumped into the receiver pipe, shown (Fig. 25) above the cylinder, and is allowed to fall, drop by drop, through a sight feed, into the hot jacket around the combustion chamber. Here the oil is converted into vapour, or perhaps a mixture of oil-gas and vapour, depending on the temperature. At the right moment this oil-vapour or gas is drawn into the cylinder through a side valve, and mixed with the right proportion of air. The explosive mixture is fired by a heated

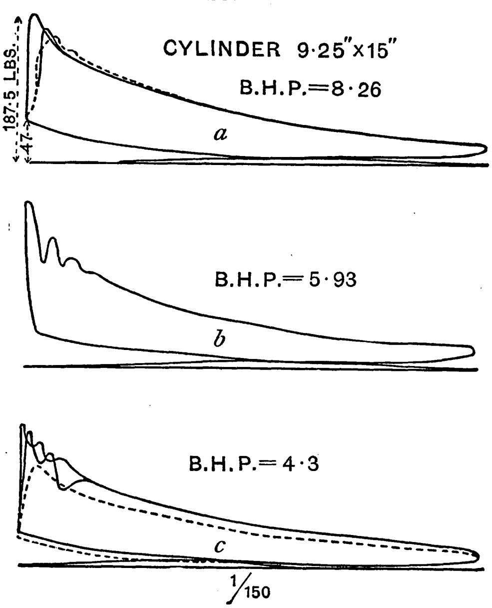
FIG. 25.



TRUSTY OIL-ENGINE.

tube, as in the ordinary gas-engine. A small air pump, on the side of the engine bed, is driven by an eccentric to blow the ignition tube flame. There is a tendency for the oil to become decomposed and to yield the tarry products which form a sooty deposit, depending on the nature of the oils used and the regulation of the vapour temperature. The cover, on the back end of the vaporiser, can be readily removed to clear away deposit, which might cause trouble in practical working.

FIG. 26.



INDICATOR DIAGRAMS TRUSTY OIL-ENGINE.

Fig. 26 shows the indicator diagrams. The rounding of the compression and explosion curves is probably due either to the compression space in the cylinder being too small, or it may be due to premature ignition. It appears that the charge is trying to burn, but cannot until the piston turns the dead point and allows the glowing mass to expand. On the other hand, the dotted diagram Fig 24, *a*, shows late firing of charge.

The normal speed of this engine is 230 revolutions per minute. The consumption of oil, either Broxburn Lighthouse or Royal Daylight, is said to be less than a pint per hour per brake horse power.

OTHER OIL ENGINES.

There are several other petroleum oil-engines—as the Crossley oil-engine and the Robey portable oil-engine—belonging to one or other of the three classes described. We have merely taken representative engines, and must now pass very briefly in review some important points touched upon as common to all.

Considering the attention that is being given to the oil-engine by many leading engineering firms, we may expect rapid advancement and improvement in this class of prime motor, which bids fair to take the place of small steam and gas engines.

MIXING AND PREPARATION OF CHARGE.

Hitherto the most satisfactory mode of dealing with the oil is that adopted in the Priestman engine, namely, spraying the oil, and slightly heating the spray cloud, under ordinary atmospheric pressure, in a large vaporiser, then adding the right proportion of air automatically, to give complete combustion; so that, once the engine is started, there is no exposed flame, and the small condensation of oil in the cylinder serves as a perfect lubricant. Considerable saving is effected by the regenerative principle of utilising heat of exhaust to vaporise incoming charges of oil and air. In some instances, this engine has worked for more than a year without requiring cleaning.

In most other oil-engines there is a difficulty in regulating and maintaining a suitable temperature in the vaporiser, and in mixing the exact proportions of air with different oils, to form an explosive mixture that will burn completely without leaving troublesome deposits in the engine in ordinary working.

Usually, 5 to 15 minutes are required to heat up vaporiser when starting, and in this respect the gas-engine is perhaps somewhat better adapted to intermittent work. At the same time, there are many instances on record of gas-engines requiring a longer time than this to get started.

FIRING OF CHARGE.

In these oil-engines the charge is usually fired either by (1) incandescent metal tube, as in the Trusty and Crossley engines; or (2), by compression into a heated chamber, as in Hornsby-Akroyd, Capitaine, and Robey portable; and (3) by the electric spark, as in the Priestman engine.

Of these methods the incandescent metal tube is most commonly adopted in gas engines.

But we must be careful not to run away with false notions or conclusions by allowing gas-engine experience to bias our judgment too much about firing the charge of oil-vapour and air, because not only is the nature of the

explosive mixtures to be fired very different in the two cases, but also the conditions of working and governing these charges.

In the one case you have to fire gas, and in the other oil-vapour.

In the first method, the metal tube must be heated to incandescence by an oil lamp, and this is not very satisfactory, because there is always the tendency to have a more or less sooty deposit and unpleasant smell indoors, whilst in many positions a naked light is very objectionable, and gives trouble when exposed to wind and weather. The igniting tube may give way when least expected in the middle of a run, and the engine must then be stopped to renew the tube, no matter how critical the moment. The action of a timing valve shortens the life of an ordinary wrought-iron tube to about thirty working hours; special tubes, containing aluminium and other metals as alloys are said to last several months. Wrought-iron tubes on gas-engines rapidly swell and deteriorate, forming crystalline layers of a carbide of iron, which you see by the old broken tubes on the table. As the material in these thick layers is a bad conductor of heat, a stronger flame becomes necessary to heat them through to the inside, and ignition becomes uncertain until at last the tube bursts, and, if the engine is not stopped, may cause serious injury. Moreover, there is further trouble with the carbon deposit inside metal tubes used on oil-engines, unless the temperature of the whole tube is very high. Porcelain tubes have been tried on the Capitaine, but experience shows that these are open to the objection which affects glass and earthenware material, viz., that when intensely heated and subjected to sudden cooling action, they shiver in pieces, as when cold water is thrown on hot glass. In the Capitaine engine, after the night's rest, there is aqueous vapour condensed in cylinder and porcelain tube, which prepares it to be broken when suddenly heated at starting.

Again, the heated tube cannot be raised to such a high temperature as the electric spark, and, therefore, cannot give so powerful and certain an ignition as we obtain in the Priestman engine.

Ignition by the electric spark is even recommended for gas engines by Monsieur Edward Delamare-Deboutteville, of Rouen, in his interesting and instructive paper*, read before the Institution of Mechanical Engineers in Paris, at the International Exposition of 1889. He says:—"During a course of experiments on all the systems of ignition known, the paramount importance of a thoroughly good ignition has been conclusively proved. For safe working it is indispensable to have a perfectly certain ignition; .... and as a powerful ignition is a condition of immense importance, this condition is only fulfilled by the electric spark. All the methods of ignition by flame have proved inferior to it in this respect, including the superheating of a platinum wire by a flame, and the expedient of raising a *thin* tube to a red heat."

Moreover, the charge can be fired by the electric spark at any desired part of the stroke, which is a great desideratum, with perfect precision and greatest rapidity, several times in a second.

Throughout long runs in a Priestman engine doing duty with the ordinary kerosene oils, there is no deposit on the porcelain insulator. Of course it is easy to raise a deposit if you wish, but with ordinary care this may be almost entirely avoided, although with the heavy oils there is at times a slight deposit. So perfect is the combustion in the engine cylinder, that if a plug be covered with soot or carbon, and fixed in the engine, it will be cleaned in the act of running.

The battery only wants renewal, the prepared charge consisting of 8 ozs. bichromate of potash, finely powdered and dissolved in 80 ozs. of water, and 6 ozs. of fluid sulphuric acid (H_2SO_4) is added to the solution in which the zinc plates are placed. This charge should last 30 working hours, and when the spark becomes weak, an additional 3 ozs. of sulphuric acid revives the battery and prolongs its life by 10 or 20 hours more.

Experiments made to find the life of one of these bichromate cells showed that battery life, with continuous spark, was 76 hours 55 minutes; whereas with contact make and brake arrangement, as in Priestman engine giving intermittent spark, the cell lasted 126 hours 40 minutes; thus proving that the intermittent spark is much easier on the battery than a continuous discharge.

Cost of Ignition.

Further, the cost of working this electric igniter is small, and compares favourably with that of the heated tube. Taking the average working life of the battery in the Priestman engine to be, say, 40 hours, buying

* See paper, "Gas Engines," Proc. Inst. Mech. Engineers, p. 500; also *Engineering*, August, 2, 1889.

the chemicals at wholesale prices, and making them up according to the above recipe, the *cost per day of ten working hours*, including zinc, would be about 1d. or 1¼d. Suppose the user gets his materials at local rates, allowing the retailer a profit of 50 per cent. over the wholesale prices, the cost of the battery would not be more than 1½d. to 1¾d. a day, no matter what the power of the engine.

Let us see how this compares with the case of the heated tube ignition. We shall take the figures obtained by Mr. W. Worby Beaumont during a trial of the Weyman "Trusty" oil-engine last December. The igniting tube was heated by a flame from oil lamp, which used 0·58 lb. of oil in 3½ hours of working; that is, at the rate of 1·66 lb. during ten hours, or one day. The Broxbourne Lighthouse oil used was of specific gravity 0·810, and the price 6·5d. per gallon of 8·1 lb. Consequently the 1·66 lb. of oil used cost 1⅓d. A new wrot-iron tube costs 2d., and lasts about 30 or 40 hours, so that the cost of renewal is from a ½d. to ⅔d. per day of ten hours; total cost comes out 1⅚ to 2d. a day.

Hitherto, we have had more to do with heated tube ignition in gas-engine work, and the gas consumption for this purpose alone in the Atkinson engine varies from 4·5 to 5 cubic feet per hour. If the price of gas be 2s. 6d. a 1,000 cubic feet, the gas bill for heating the tube alone comes to 1⅓d. or 1½d. per day. In some gas-engines wrot-iron tubes last about 30 hours, and at 2d. a piece, costs ⅔d. a day. So that the total cost in this case is also about 2d. a day of 10 hours.

There appears, therefore, no practical gain in pence by using gas to heat the ignition tube, although it is much cleaner and more convenient than oil when the engine uses gas.

Furthermore, the electric ignition has several important advantages in oil-engines. The plug, when screwed into the cylinder, has the platinum points inside the cylinder, so that the spark works equally well out in the open air exposed to wind and weather. There is no naked flame, and therefore it may be used in a coal mine. The contacts can be adjusted to have the spark at the desired moment. If the spark becomes weak, a little more sulphuric acid added to the battery enables you to continue running the engine, and you are not obliged to stop for renewal, as in the case of the heated tube bursting. The charge or dose of chemicals for the battery is made up and supplied by the makers of the engine, and any ordinary labourer can add the necessary water.

Methods of Governing.

There are two methods of regulating the speed for varying load in oil-engines, by the governor, either (1) *entirely cutting off the oil supply to the cylinder* for one or more working strokes, when the speed is too high or (2) *varying admission or partial cut-off*; that is to say, varying the amount of oil and air-supply to engine, thus forming a more or less powerful explosive mixture, according as the engine speed is slower or faster than the normal.

1st. In most gas-engines the simplest and most effective governor completely cuts off the supply of gas, and thus reduces the number of explosions, when the speed is too fast, until the normal speed is reached, and then the regular quantity of gas is again admitted. In engines of the Otto cycle, with only one explosion in two revolutions, one miss-fire means that the piston does not receive an impulse during at least 3½ revolutions, and this renders it difficult to maintain uniform speed, especially when the load is suddenly increased soon after the charge is cut off. In this way the speed is seriously reduced. Moreover, the air has, in the meantime, swept out the residual products, and the cylinder is slightly cooled; so that, when gas is again admitted, the mixture being undiluted, gives a more powerful explosion than usual, so that the speed changes rapidly.

The same holds true for oil-engines.

In order to ensure greater regularity of running, and overcome slight fluctuations in load, larger fly-wheels are used, and the engines run at much higher speeds than heretofore.

2nd. The second method has not been generally adopted in gas-engines. It is found that, with either too little or too much gas, the weaker and stronger charges formed are likely to be non-explosive; consequently, there is no explosion, and the charge is lost or passed into the exhaust, where it remains until the hot products from the next explosion ignite the unburnt gases in the exhaust pipe, giving explosions with unpleasant cracks or reports. The gas is thus expended to no useful purpose, as these explosions in the exhaust pipe merely tend to annoy neighbours or frighten sparrows.

In the case of oil-engines it is different.

For instance, we have already seen in the

Priestman spray-maker that the amount of air is adjusted by the wing throttle valve to suit the oil passing through the oil-plug, and that the governor adjusts them both simultaneously by turning the spindle or oil-plug, so as always to form an explosive mixture, no matter whether the charge is a weak or strong one.

The indicator diagrams, Fig. 17 (p. 988) show clearly the effects of this mode of governing on the behaviour of the charge in the cylinder. When the speed is too fast, a weak charge is formed, which gives a slower and later combustion in the cylinder, the mean effective pressure on the piston being thus reduced. Moreover, since the amount of oil and air entering the cylinder is reduced, the compression is not so high, and, therefore, the combustion is slower and not so perfect. The impulse every revolution gives steady smooth running, with gradual and not spasmodic variations in speed.

RESULTS OF PRIESTMAN ENGINE TRIALS.

In order to obtain practical results from different oils working in the same engine, I made a series of trials of a 5 horse-power Priestman horizontal engine, of the newest design, with cylinder $8\frac{1}{2}$ inches diameter and 12 inches stroke. The volume of clearance space in the cylinder 370 cubic inches or 0·2141 cubic foot. An ordinary-rope brake was on the flywheel of effective diameter 4·64 feet.

The typical samples of ordinary burning oils tried were the Broxbourne Lighthouse oil, Royal Daylight, Russian Ordinary or Russolene, and Russian Lustre, tested as in Table I., p. 964, and analysed with particulars given in Table IV.

TABLE IV.—OILS USED IN TRIALS.

Brand of Oil.	Specific gravity at 60° Fahr.	Flashing Point, Abel Test. Fahr.	Chemical Analyses.		Wholesale price per gallon, delivered naked in London and Liverpool.
			Carbon in 1 lb. Oil.	Hydrogen in 1 lb. Oil.	
Lighthouse	0·810	152°	0·8601	0·1390	$4\frac{7}{8}$d.
Daylight	0·796	76°	0·8462	0·1486	$4\frac{1}{2}$d.
Russolene	0·824	82°	0·8588	0·1407	$3\frac{5}{8}$d.
Lustre	0·825	—	0·8600	0·1395	$3\frac{1}{4}$d.

After preliminary trials, the engine was run for several hours with full load, half load, and light. Table V. gives some of the results obtained with various oils.

The indicator diagrams, here on the table, and the set shown in Fig. 17 (p. 988) are average samples of those taken. The vacuum at end of suction stroke was about 5 lb. per square inch below atmospheric pressure, and about 7 lb. per square inch when running light. The pressure at end of compression stroke, from 25 to 28 lb. per square inch for full load, was reduced when governing to 12 lb. per square inch for half load, and then the highest explosion pressure, Table V. (p. 1004) was only reached in some cases about one-quarter stroke owing to the slow gradual combustion.

Broxbourne Lighthouse oil gives decidedly the best results, both as regards power developed on the brake and shown by the indicator diagram; but its present high price tends to prohibit its general use. It is a safe oil, homogeneous in composition, and can be vaporised within a limited range of temperature below 300° C., as shown by fractional distillation curves, p. 967. Consequently the more rapid and complete is its combustion in the engine cylinder, giving a much higher pressure and better diagram than any of the other oils tried.

As regards the

CONDITIONS FOR ECONOMIC WORKING,

it would appear that the compression chamber or clearance space in the cylinder should be somewhat smaller in the case of Lighthouse and Russian Lustre than for Russolene and Royal Daylight oil. The clearance is reduced by simply fixing a plate on the end of the piston.

TABLE V.—Results of Engine Trials with different Oils.

		Brand of Oil.

Pressures.	Explosion pressure	120	50	140	50	120	50	120	49

Take, for instance, Daylight oil in the same engine having the clearance reduced from 0·2141 cubic foot to 0·2101 cubic foot. This change increases the compression of the charge before ignition from 25 to 35 lb. per square inch, and the mean effective pressure from 47 to 53 lb. per square inch, thus increasing the power developed by the engine, running at the same speed, from 7·05 to 7·72 brake horse-power.

As a matter of fact, for any particular oil experience alone must decide the degree of compression before ignition that gives best results as regards power, efficiency, and economy, consistent with durability of the engine. In several sets of trials made with another oil-engine of the Priestman type, it was found that Lighthouse oil also gave out the greatest power. Again, experience shows that these ordinary lamp oils differ slightly in their order of merit in a 5 horse-power engine as compared with the figures obtained in a 1 horse-power engine. That is to say, the efficiencies of different oil vary somewhat with the size, and depending upon the relative cooling surfaces of these engines. Therefore, the dimensions of engines have to be taken into account, when determining the most suitable kind of oil to be used therein. At the same time, for some of the best oils, the difference is not very great. Thus, "Royal Daylight" works very well in small engines, whereas, in larger engines, "Russian Lustre," which is a cheap oil, can be used to advantage; and, doubtless, the price of an oil must stand as an important factor in the way of its adoption for use in this class of prime movers.

The efficiency might be pushed much further, but practical considerations, and the conditions of everyday work, render it absolutely necessary, for steady constant running, that the temperature of the cylinder must be kept down, to allow of proper lubrication. After all, the tests (Table V.) show that 14 or 15 per cent. of the total heat of combustion of the oil is turned to useful mechanical energy on the brake; that is, a consumption of less than 1 lb. of oil, costing about ½d. per hour per brake horse-power.

These tests and figures abundantly prove that we have now, at least, an oil-engine which is thoroughly reliable and steady, having already done good work, without special care or attention, for a year or two, and using, in a most economical manner, the safe common burning oil that can be obtained in every country village.

There are, unquestionably, many positions in which the oil-engine will prove of great practical utility, and, for small powers—at least up to 20 h.p.—take the place of both gas and steam-engines.

Miscellaneous.

PATENT FEES.

The reduced scale of patent taxation—which the industrial community owes to the late Chancellor of the Exchequer and the late President of the Board of Trade—came into operation on October 1. In order to understand and appreciate the nature of the boon which Mr. Goschen and Sir Michael Hicks Beach have conferred upon inventors, it is necessary to glance back at the history of patent taxation in this country. Previous to the year 1852, Letters Patent, issued under the Great Seal of England, extended to England, Wales, and Berwick-on-Tweed alone, and cost in stamps and fees nearly £150. If the patentee desired to have his invention protected in Scotland and Ireland he was obliged to take out a separate grant for each of these countries, at a cost of about £85 in the former case, and £150 in the latter. The cost of taking out and maintaining for the full term of fourteen years allowed by the Statute of Monopolies a patent which was operative in every part of the United Kingdom, fell little short, therefore, of £400; and this heavy tax had, moreover, to be paid by the patentee practically at the time when his patent was issued. In 1852, however, the Legislature, acting upon the report of a Parliamentary Committee, before which the most distinguished experts of the day had given evidence, inaugurated an important departure from the old *régime*. The Patent-law Amendment Act of 1852 extended the scope of Letters Patent to the United Kingdom, the Isle of Man, and the Channel Islands; reduced the patent-tax from about £400 to £175; and enabled a patentee to pay the heaviest part of it in two instalments of £50 and £100 before the expiration of the third and seventh years respectively of the patent term.

The full significance of this change in the policy of the State towards inventors is not, perhaps, superficially apparent. It was not merely that the patent fees were cut down to less than half their former amount. The patentee was now enabled, by the comparatively trivial payment of £25, to have his invention protected throughout every part of the United Kingdom for three years; on payment of the first renewal fee of £50 before the expiration of the third year of the term, the protection was extended for another four years. The practical effect of the new statute, therefore, was to give him the benefit of

a "sliding scale of duration," such as we find in many continental patent systems. But this was not all. Under the old law a patentee had been obliged to pay practically the whole tax at the commencement of the term, not only before his invention had begun to be a source of profit, but just at the very time when he had to incur the most serious outlay in order to establish it and commend it to the public. The postponement of the heavier payments till the middle and latter end of the term relieved him from this grave and often ruinous obligation, and enabled him to determine whether the continuance of his patent was advisable. In 1884, the Board of Trade—of which Mr. Chamberlain was then President--introduced other and not less important reforms in the scale of patent taxation. In the preceding year, the Legislature had abolished the numerous minute and complicated stages through which, under the Act of 1852, a patent had to pass before it received the impression of the Great Seal. It was felt that the preliminary fee of £25 was no longer justifiable, now that the procedure in connection with the grant of Letters Patent had been simplified, and it was, accordingly reduced to £4 in the first rules made by the Board of Trade under the Patents Act of 1883. The renewal fees of £50 and £100 were not reduced, but the time for paying them was extended from the third and seventh to the fourth and eighth years respectively of the patent term, and an alternative system of payment by annual instalments, commencing at the fourth year from the date of the patent, and varying in amount from £10 to £20, was established.

Mr. Goschen's skilful financial policy, the increasing volume of the patent business of the country, and the careful husbandry of the resources of the Patent-office, for which the Board of Trade has in recent years been so often, and so unjustly, censured, enabled the late Government to signalise its departure from office by the promulgation of the Patents Rules, 1892, which came into force on Saturday last, and make material reduction in the scale of patent taxation. The preliminary fees of £4, which protect an invention for four years, are still payable, and so long as the law permits a man to patent practically anything that he chooses, we fail to see how they can, with any advantage to the public, be very much reduced. But the renewal fees are diminished in the most wholesale and generous way. The instalments of £50 and £100 are abolished, and the system of annual payments, which was optional under the old rules, is now to be the recognised mode of taking out a certificate of renewal, although the patentee may, of course, pay the whole or any portion of the aggregate of the prescribed annual fees in advance. In lieu of the fee of £10, which was formerly payable before the expiration of the fourth, fifth, sixth, and seventh years of the term, fees of £5, £6, £7, and £8 are now prescribed. Fees of £9 and £10 replace the old fee of £15, which had to be paid before the expiration of the eighth and ninth years from the date of the patent, while fees of £11, £12, £13, and £14 are substituted for the fixed fee of £20, which has hitherto been payable between the tenth and thirteenth years of the grant. The entire cost of obtaining a patent and keeping it up for fourteen years has thus been reduced from £154 to £99. The fees of £3, £7, and £10, heretofore payable for one, two, or three months' extension of the time for the settlement of the annual instalments, have also been diminished to £1, £3, and £5 respectively. In the not distant future—when the reconstruction and reorganisation of the Patent-office have been completed, and the experiment, now commencing, has been justified by results—it may be possible for the Board of Trade to recommend still more radical changes in the scale of patent taxation. In the meantime the country will receive the valuable concessions which the new patent rules contain with a grateful recollection and recognition both of the spirit that prompted them, and of the skill that rendered them possible.—*Standard*:

Obituary.

SURGEON-GENERAL BELLEW, C.S.I.—Dr. Henry Walter Bellew, the eminent Oriental scholar, who died on 26th July last, read a paper on the "Injurious Effect of Canal Irrigation on the Health of the Population of the Punjab, and their remedy," before the Indian Section on May 4, 1888, and shortly afterwards was elected a member of the Society. Dr. Bellew was the son of Brevet-Major H. W. Bellew, killed during the retreat from Cabul in January, 1842. After some months experience of the Scutari hospital, and of sick and wounded troops on board a transport during the Crimean war, he sailed to Calcutta in 1856, and on his arrival he was placed in charge of the Corps of Guides on the Peshâwar frontier. He was associated with several important missions, and in 1869 he was appointed interpreter in the suite of the Amir Sher Ali Khan, when his highness attended the Umballa Durbar. In 1877, Dr. Bellew was appointed Sanitary Commissioner, Punjab. He retired in 1886, and settled in England. He was distinguished as a linguist, and published a dictionary and grammar of the Pushtu langauge. Amongst his other works may be mentioned—"From the Indus to the Tigris," "Kashmir and Kashgar," "Afghanistan and the Afghans," "The Races of Afghanistan," and a "History of Cholera in India, from 1862 to 1882."

UNION OF INSTITUTIONS.

The following institution has been received into union since the last announcement:—

Manchester Athenæum, Manchester.

Chicago Exhibition, 1893.

PHOTOGRAPHIC COMMITTEE.

A meeting of the Photographic Committee was held on Wednesday, 26th inst. Present: Francis Cobb (in the chair), George Davison, James Dredge, Colonel J. Gale, and Sir Henry Trueman Wood, secretary to the Royal Commission.

DEDICATION CEREMONIES.

The following account of the opening ceremonies, on the 21st inst., is taken from Reuter's special report:—

By a series of imposing ceremonies, the great "park of palaces," in which the World's Fair is to be held next year, was formally dedicated to-day. The principal ceremonial took place in the Manufactures and Liberal Arts Building, in the presence of 100,000 spectators. This building is the largest structure that has ever been erected, and the assemblage which it accommodated to-day is the largest which has ever been brought together beneath a single roof. The audience, it may further be said, contained the most numerous and most representative gathering of distinguished Americans that has ever been seen. At nine o'clock this morning, most of those who intended to take part in the great procession which preceded the indoor ceremony assembled in the Auditorium, and proceeded in carriages in processional order to the World's Fair grounds.

The procession was formed near the Auditorium, in Michigan Avenue. It was escorted by cavalry and light artillery, and consisted of a long array of officials, members of the Government, of the Senate, of the House of Representatives, the Diplomatic Corps, the Judges, representatives of the army and navy, the Governors of the States and Territories of the United States, and the City Council of Chicago. A specially-interesting feature in the gathering was the presence of women, representing each of the 13 original States. The Board of Lady Managers, headed by their President, were also present. Vice-President Morton attended in the absence of President Harrison, due to the illness of his wife; and, among other prominent men present, were ex-President Hayes and Cardinal Gibbons. The Commissioners of foreign nations at the Fair filled 15 carriages, and the foreign Consuls five. Thirty more carriages were occupied by the other Columbian Commissioners. The architects of the Fair buildings were also present.

Passing through the streets to Washington-park the procession formed in parallel lines on the west side of the parade grounds. On the opposite side the National and State troops had meanwhile been drawn up in brigades. The whole formed a brilliant array. The troops presented arms and a Presidential salute was fired by a battery of artillery. A national salute was also fired as the long line of carriages filed into the Show grounds. The troops on parade, including infantry, marines, and militia, numbered over 15,000. They came from Ohio, Indiana, Missouri, Michigan, Wisconsin, and Illinois.

It was nearly two o'clock when the band of music announced to the multitude in the vast building that the procession had arrived. The cavalry escort at the head of the column rode in full marching order directly through the portals into one of the wings flanking the structure on each side. They then took up their places with the other regular troops beneath the side gallery. The staffs of the State Governors and other military men of rank took their seats on the grand stand, their variegated uniforms making up a brilliant mass of colour. A few minutes later a great cheer went up as the vanguard of the officials and guests appeared upon the platform. At their head was Mr. Lambert Tree, formerly American Minister at St. Petersburg, acting as escort to the foreign Diplomatic Body. Baron di Fava, the Italian Minister, Doyen of the Corps Diplo-

matique at Washington, leaned on Mr. Lambert Tree's arm.

The chorus, at a given signal, struck up a "Columbian March," written for the occasion by Professor Paine.

After the singing of the "Columbian March," prayer was offered by Bishop Charles H. Fowler, of California.

An introductory address was then read by the Director-General, as master of ceremonies. It was followed by an address of welcome by by Mr. Washburne, Mayor of Chicago.

A dedicatory ode, by Miss Harriet F. Monroe, of Chicago, was then partly read and partly sung. The stanzas selected for musical rendering were given with magnificent effect by a chorus of 5,000 voices.

The master artists of the Exhibition were next presented to the President of the Exhibition, and were each handed commemorative medals. The chorus having sung Haydn's "The Heavens are telling," the buildings were formally handed over for dedication. Vice-President Morton having performed this ceremony, and the full chorus and orchestra having rendered "The Star-spangled Banner" and "Hail Columbia," Mr. Chauncey Depew delivered the Columbian oration.

More music followed, and prayer having been offered by the Rev. John Ireland, Archbishop of St. Paul, the Benediction was pronounced by the Rev. Mr. Maccook, of Philadelphia.

The day was observed as a general holiday in almost every part of the country, and in many other cities the occasion was celebrated by banquets and other festivities.

Mr. Alfred Carpmael and Mr. John Biddulph Martin, Members of the Royal Commission, and Colonel Grover, R.E., attended the ceremonies, as representatives of the British Section.

Proceedings of the Society.

CANTOR LECTURES.

USES OF PETROLEUM IN PRIME MOVERS.

By Professor W. Robinson, M.E.,
Assoc. M.Inst. C.E., University College, Nottingham.

Lecture III.—Delivered March 14, 1892.

Oil-gas Producers.

In our last lecture we considered some of the practical and successful solutions of the problem—how to use common refined petroleum oils, instead of gas, as fuel in the cylinder of the internal combustion engine. One difficulty is to convert all the oil into vapour, when preparing the charges, without forming oil-gas, because the tarry products given off with the gas at high temperatures cause trouble in practical working. Here the vaporiser tends to become a gas generator as the temperature is increased and the oil heated alone.

The idea is to have the total heat of combustion of the oil vapour available, and, at the same time, to take advantage of the high efficiency of the internal combustion engine. Several engines even utilise some of the heat of the exhaust gases from the previous explosion to vaporise the oil for the incoming charge.

Notwithstanding these laudable attempts in the right direction, it is found that, if the oil be in the state of liquid or vapour, it is difficult to obtain complete combustion except with a seriously excessive amount of air over that required according to the chemical analysis of the oil.

From the above, it follows that in large petroleum oil-engines the ordinary vaporisers are somewhat troublesome to work with, although they offer special facilities for the application of the Stirling regenerative principle to utilise some of the waste heat of the exhaust.

It appears then that, for large engines, another practical plan is to convert the cheap and heavy hydro-carbon oils into true and fairly pure gas, by means of a simple oil-gas producer. This oil-gas, when washed and cooled, can be used with economy in the ordinary gas-engine, which may thus give motive power in a country district where there is no coal-gas supply.

Loss in Gas-making.

Of course some of the heat of combustion is lost in the operation of preparing the gas; still, in spite of this loss, a decided saving in fuel may be effected by the *combination of oil-gas producer with gas-engine*, instead of the *steam boiler and steam engine*, in places where intermittent work is required, suitable oil cheap and plentiful, and where the price of coal is high.

On the other hand, more heat may be produced by the direct combustion of the oil than by first converting the oil into a gas before

using it as fuel. This is obvious when we bear in mind that it is impossible to create energy by any round-about process, however mysterious; and that there must necessarily be some loss in every process of gasifying fuel.

Take for instance 1 lb. of coal of calorific value 14,200 British thermal units, that is 1 lb. of coal which gives out by complete combustion heat energy equivalent to 14,200 × 772 or in round numbers nearly 11,000,000 foot-pounds. Now this 1 lb. of coal, by destructive distillation in a retort, will yield an average of 4·5 cubic feet of ordinary coal-gas, which, when completely burned, gives out 4·5 × 500,000, or about 2,250,000 foot-pounds of energy. Thus the coal-gas does not even give out in burning one-fourth of the total heat of combustion of the parent coal. Of course the coke resulting from the coal is valuable as a heating agent.

Again, with Dowson's gas apparatus 1 lb. of coal of calorific value equivalent to 11,000,000 foot-pounds of energy, will produce 70 cubic feet of gas capable of giving out in burning, a total amount of heat equivalent to 70 × 124,000, or 8,680,000 foot-pounds, showing that a considerable loss occurred in the gas-making process. Nevertheless, when this gas is used in an Atkinson cycle gas-engine of 16·7 horse-power, we find 1·067 lb. of solid fuel, consisting of 0·877 lb. of coal and 0·190 lb. coke, is capable of giving one indicated horse-power per hour, and 1·25 lb. gives an effective horse-power per hour; and in a large Crossley 118·7 horse-power gas-engine even better results are obtained, the expenditure of fuel being ·883 lb. per indicated horse-power, and 1·033 lb. per effective horse-power per hour. Very few steam-engines would give anything like so good a result, the average of large condensing steam-engines requiring 1·75 lb. of coals per indicated horse-power, or 2 lb. per effective horse-power per hour; and small non-condensing steam-engines use 5 lb. per indicated horse-power and 6 or 8 lb. of coal per effective horse-power per hour.

From a commercial point of view, the price of a producer and a steam boiler are much the same, and they might be taken to have the same efficiency, viz., 70 per cent. That is to say, of the total heat of combustion of the coals, 70 per cent. is found in the steam in the one case, and in the gas formed, available for gas-engine work, in the other.

Gas-engine *versus* Steam-engine.

The efficiency of the best steam-engine is about 10 per cent., and that is a very high figure for the ordinary run of steam-engines. That is, of the total heat available in the steam supplied to a good steam-engine, only 10 per cent. is converted, or appears as useful work. All the rest of the heat supplied in the steam is rejected by the engine or lost in various ways.

With gas-engines, an efficiency of 18 per cent. is common.

Comparing the combination, therefore, of a steam-engine and boiler with that of a gas producer and gas-engine, when the same fuel is used in both, the combined thermo-dynamic efficiencies are 7 to 10 per cent. of the total heat of the fuel in the case of the steam-engine and boiler, as against 12·6 to 15 per cent. in the case of the gas producer and gas-engine.

Thus, the simple and direct way to compare the efficiency of these combinations is to take in each case the weight of fuel (coal) used per effective horse-power per hour, and have the same kind of fuel used in both. In such a case it is no more necessary to know the volume of gas than the volume of steam used. If different fuels were taken, then we should compare the cost of working and the absolute efficiency, or the fraction the useful work done is of the total heat energy supplied in the fuel.

Here we have the important fact brought out, that the gas-engine has very much higher efficiency, as a heat-engine, than the steam-engine, even of the very best modern type.

Mind you, this is a comparison between the young, small, somewhat noisy, gas-engine, with its great future possibilities, and the large condensing steam-engine, practically perfect, from a mechanical point of view, and therefore "so much the worse for the steam-engine."

Further, in the petroleum-engine, which uses the oil directly in the cylinder, as oil without the 30 per cent. loss in the gas producer, we have already found a still larger proportion of the total heat of combustion of the oil converted into useful work.

The gas-engine, with its high efficiency, can be worked equally well with oil-gas; and, in this way, *heavy oils* can be employed for obtaining motive power, which cannot be used without trouble in the oil-engine proper.

Naphtha Vapour is not Oil-gas.

Of course we cannot ignore the obvious fact that the forbidden thing is always tempting to human nature, and, as a rule, is easily done, if it were not for the necessary precautions laid down and enforced by law for the public good. There is a great temptation to use deodorized

naphtha, of specific gravity from 0·7 to 0·77, instead of ordinary burning oils of specific gravity ·795 and upwards, in the petroleum-engine, because of the more complete combustion of the volatile spirit without residue or deposit and the greater power obtained therefrom. Again, a so-called oil-gas, or carburetted air, can be easily produced, by passing air through light petroleum spirit; but the explosive mixture thus obtained is not a true gas, and merely consists of air laden with petroleum vapour. This petroleum spirit is highly inflammable and dangerous, and should not be made use of or placed in the hands of unskilled persons, because it may explode, and cause serious mischief when least expected. It is not gas that arises from naphtha, but vapour; consequently, like all vapour, it condenses again at moderately low temperatures when subjected to pressure.

Oil-gas.

On the other hand, oil-gas made by splitting up by heat intermediate shale oil and the like oils, into a real and fixed gas, does not condense again appreciably at the coldest temperature in winter. Real oil-gas does not possess the dangerous and troublesome qualities referred to. Moreover, in case oil-gas escapes from a leaky pipe, it can at once be detected by its strong smell, like coal-gas.

In this respect oil-gas is superior to water-gas, that is, hydro-carbonic oxide or producer gas, which is scarcely perceptible by its smell, and consequently requires to be odorised, and due care taken to avoid bad joints in piping. Otherwise water-gas will by degrees imperceptibly overpower and poison those inhaling it, owing to the poisonous constituent carbonic oxide.

Oil-gas, then, which burns with excellent results in the gas-engine cylinder is a safe, rich, true gas, now generally made from petroleum oils and fats, too heavy to be easily dealt with in the ordinary oil engine cylinder, and which may be had at low prices. Thus the oil-gas plant comes in, as an auxiliary to the gas-engine, just where the oil-engine of the Priestman type finds trouble or stops.

Oils Suitable for Oil-gas Making.

It is curious to note that the light thoroughly refined burning oils, as common paraffin oil and petroleum, which answered best in the Priestman engine, do not make so good oil-gas as the partially refined petroleum and the heavier oils. Of these oils there is a great variety represented by the few samples before you on the table.

We have here a Scotch intermediate oil, got from Shale Works in Linlithgow, and called gas-oil, of specific gravity, varying from ·840 to ·865, and lowest flashing point 235° Fahr. close test. This oil costs £4 15s. a ton, and can be turned into very good oil-gas at the rate of 80 to 95 cubic feet per gallon. There is another intermediate oil of somewhat similar nature, from America, which costs £5 a ton in Liverpool, and would produce about 100 cubic feet of gas per gallon.

Even the still heavier oils, as Russian astatki or residuum from the distilleries and refineries of Russia, and the American residuum, also make excellent gas, one gallon producing about 100 cubic feet of oil-gas.

Apart from these mineral oils altogether, we may turn for a moment to the *vegetable* world, and find, for example, on the West Coast of Africa abundance of *palm oil* which yields excellent gas. So does *cocoa-nut oil* from the cocoa-nut palm. This sample is in the solid state, but it can be readily melted by a Bunsen burner. Then, of *animal oils*, in Australia the grease obtained in washing sheep's wool, as well as mutton fat and dripping, produce a very strong gas at the rate of 100 to 120 cubic feet to the gallon. The squatter in Australia has lots of this stuff to hand, and can easily make it into gas to drive the ordinary gas-engine.

In short, nearly all these fats and heavy oils can be converted into gas by suitable appliances.

Oil-gas Manufacture.

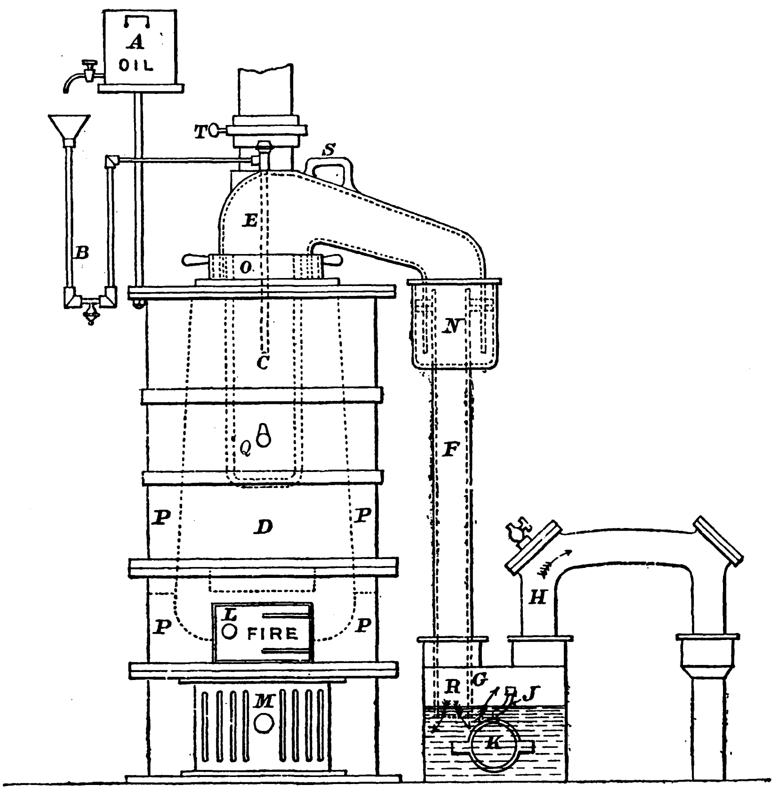
Gas is now generally made from *intermediate oil* or partially refined paraffin oil, by allowing the liquid to flow from an elevated cistern in a thin continuous stream, usually through a syphon, into hot quarters, where it is *vaporised* into a cast-iron retort at a bright *cherry-red* heat, which decomposes and converts the vapour into a "fixed" or permanent gas mixed with tarry products. The gaseous mixture is then allowed to pass freely through a wide pipe into a *hydraulic main* filled with water, which separates most of the tarry matter, and after further *washing* and *cooling*, without any pressure being applied, the oil-gas is led to the gas-holder, where it is cooled and stored ready for use in the gas-engine. This is the simple process adopted in small oil-gas plant.

For lighting purposes, the gas, after leaving

the hydraulic main, is taken through another water washer, and purified on its way to the gasholder by passing over a mixture of slaked lime and sawdust, in proportions of 2 to 1, spread in a layer 2 inches deep over a perforated tray. This mixture removes the sulphur compounds, carbonic acid, and other impurities. Finally, the gas is drawn from the gasometer by compression pumps, and forced into storeholders at a pressure of 150 lb. per square inch.

The quality of the gas, and the number of cubic feet obtained per gallon of oil, depend upon the *temperature* of the retort, as well as upon the *rate* at which the oil is allowed to run into it. The practical tests for regulating these during gas-making are (1) the colour of the gas, which should be nut brown, (2) a drop of the tar, from the hydraulic main, on a piece of white paper should not have a greasy border. Too fast oil supply gives a greasy rim around the spot of tar, and makes the gas white or too light brown; if dark brown, forming flakes of soot, the oil supply has to be increased and the temperature of the retort lowered.

FIG 27.



MANSFIELD OIL-GAS PRODUCER.

MANSFIELD OIL-GAS PRODUCER.

The Mansfield Oil-gas apparatus here in the room before you, and shown in section Fig. 27, is, undoubtedly, one of the simplest producers of its kind. The little model will also enable you to examine all the parts and arrangements for yourselves. (Model and actual producer were taken to pieces and the working explained.) The oil or melted fat contained in the little cistern, A, above the apparatus, is allowed to trickle down through the U tube, or syphon bend, S, into the pipe, C, leading into the retort.

This particular size of producer will allow about half a gallon an hour to flow through when working properly. The retort is heated up to the desired temperature by the fire at L, and the draught may be regulated by the grids, M, below the fire and the damper, T, in the smoke flue; whilst the colour of the retort, which should be bright cherry-red, is observed through the sight-hole, Q. The cast-iron casing, D, of

the producer is lined inside with blocks of fireclay, P, to keep the temperature uniform, and prevent loss of heat. The cast-iron retort, C, hangs by a flange on the fireclay cover, and is made thick at the bottom to stand the heat, and lasts about two years.

When *starting*, it will require an hour or two to get up sufficient heat for gas-making. The temperature is indicated by the melting of the lead seal in the annular socket, O, so that the bonnet, E, fits down into it, and the other end goes into the socket, N, kept filled with water, at the top of the standpipe, F. The lower end, R, of the standpipe dips into water in the hydraulic box, G, which is regulated by the ½ inch siphon bend, J, and the tar is cleared out occasionally at the door, K.

In *gas-making* the oil becomes thoroughly vaporised, trickling down the pipe, C, inside the retort; and the oil vapour, as it falls down, coming into contact with the sides of the retort, at bright cherry-red heat, becomes decomposed or split up and converted into a "fixed" gas and tarry products. The newly-made gas and tarry products escape through the large bonnet, E, down the stand-pipe, F, into the water, at R, in the hydraulic-box, where the tarry and other condensable products are washed out of the gas. It is important that the passage, E, should be large, to allow the oil-gas to come over freely, so that the mixture may not be subjected to the slightest pressure likely to cause condensation until the gas is washed and cooled. The gas passes by the arch pipe, H, and connecting pipes, to the gas-holder, where it is stored under pressure of only 1 inch of water, and, when cool, is ready for use in the gas-engine.

During the manufacture of oil-gas the retort must be carefully regulated, to keep the temperature uniformly at the proper point, because the quality of the gas produced depends more upon the temperature of distillation than even upon the quality of the *oil* used. The attendant can test the gas at the small tap in the arch pipe, H. The gas should be a nut-brown colour. A gentle pulsation of the lead, O, and in the water-seat, at N, is an indication of successful gas making.

With this apparatus, and Scotch intermediate oil, of specific gravity ·840 to ·865, about 8 gallons may yield 1,000 cubic feet of gas; that is, 1 gallon of oil produces 125 cubic feet, or 1 lb. of oil gives about 15 cubic feet of this rich oil-gas.

The calorific power of this oil-gas is about 864 British thermal units per cubic foot, so that these 15 cubic feet, by complete combustion, give out 864 × 15, or nearly 13,000 British thermal units, whereas the calorific power of 1 lb. of the parent coal is 19,800 thermal units. The efficiency of this small oil-gas producer thus works out nearly 66 per cent.

Again, the highest price of the intermediate oil mostly employed is £5 per ton, or about 4½d. per gallon. The fuel in the furnace costs less than 1d. per 100 cubic feet of gas made. Hence the total cost of fuel and mineral oil to make this rich oil-gas is about 6d. per 100 cubic feet. One labourer can look after both the oil-producer and gas-engine.

Now, take the average result, and we find that in ordinary working the yield is 100 cubic feet of gas per gallon, and a 12 horse-power Crossley gas-engine requires only 10 cubic feet of this gas per effective horse-power per hour; therefore, it appears that in the combination of Mansfield *oil-gas producer* and Crossley *gas-engine*, using intermediate oil, the cost of working comes out 0·6d. per effective horse-power per hour, and the fuel used is 1·15 lb. of oil per effective horse-power per hour.

Keith Oil-gas Producer.'

The first oil-gas plant used to drive gas-engines on a large scale was at Langness Point, Isle of Man, where the oil-gas apparatus, supplied by Mr. James Keith, of Arbroath, Scotland, is used in conjunction with the Crossley gas-engine to work fog-signals for the Commissioners of Northern Lights. The success of this oil-gas installation led to the still larger one on Ailsa Craig rock, Firth of Clyde.* On Ailsa Craig five Crossley gas-engines, each of 8 horse-power nominal, using oil-gas, work the air compressers for the siren fog signals.

Through the kindness of Mr. Keith I have here on the table one of the retorts used in his oil-gas producers. This retort is of cast-iron formed in this peculiar saddle-like shape, and inside of it, there are placed shallow cast iron gutters, into which the oil dripped and trickled down towards the hotter parts of the retort, where it is converted into gas, and led off through large passages to the hydraulic box to be washed, cleansed, and cooled. The main thing is to allow the gas free play when formed and to have it washed, and cooled before being subjected to pressure.

* See paper by David Alan Stevenson in "Proceedings Inst. C.E.," Vol. lxxxix, session, 1886-87.

In the retort-house there are three benches of Keith's oil-gas producers, having four iron retorts in each; 100 gallons of ordinary lighthouse burning paraffin oil, and 20 to 30 cwt. of coal are required to heat the retorts and to make 10,000 cubic feet of gas. The retort I hold in my hand would make about 300 cubic feet an hour, and a producer will have three of these, giving about 900 cubic feet an hour.

This gas is found to be too rich to give thoroughly complete combustion when escaping into the air in ordinary way, and especially the small burners for flame ignition gave some trouble. Hence, before use in the gas-engine, the oil-gas is mixed with about one-half its own volume of air, 35 parts of air to every 65 parts of gas, in order to bring it down to about the same strength as ordinary coal-gas, so that it can be used in the gas-engine without specially changing the valves, at the rate of 26 cubic feet of this mixture containing 16·9 cubic feet of the rich oil-gas per effective horse-power per hour.

The cost of the ordinary lighthouse paraffin oil used is 4½d. per gallon, yielding 100 cubic feet of rich gas, and the cost of coals for heating retorts, reckoned at 9·6d. per cwt. delivered, brings up the approximate cost of rich oil-gas 6·9d. per 100 cubic feet, exclusive of attendance. The cost of working comes out 1·16d. per effective horse-power per hour. This total cost is rather high, owing partly to the isolation of the plant, the ordinary refined lighthouse oil used, the freight, and cost of landing.

For small installations, Mr. Keith has designed a compact oil-gas producer with one double retort, bent into a **V**-shape, the section being the common ⌓-shape used in the larger retorts. The oil is well vaporised, and subjected to a bright cherry-red heat during its passage through this **V**-shaped arrangement, so that it is thoroughly gasified, and the columns of firebrick with flame playing all round, help to utilise the heat of combustion from the fire below.

Pintsch Oil-gas.

One of the best known gas producers and plant is the Pintsch* apparatus, which produces per gallon from once refined paraffin oil, 120 cubic feet of gas, equal to 40 candles, and 70 to 85 cubic feet of 50 to 60 candle-power gas. This gas is largely used for lighting of railway carriages, but is not much used for motive-power purposes, because in this country coal is so cheap that, on a large scale, the competition is rather between Dowson gas and ordinary steam, than between oil-gas and steam.

* See papers on "Compressed Oil-gas." "Minutes of Proceedings," Inst. C.E., vol. xciii., p. 298, *et seq.* *Ibid*, vol. xcv., p. 218, *et seq.* *Ibid*, vol. cx., p. 324, *et seq.*

Thwaite Oil-gas Generator.

The wall diagram shows the section, Fig. 28 (p. 1014), of a simple retort oil-gas generator, designed by Mr. B. H. Thwaite for the gasification of partially refined petroleum oils, intended to produce oil-gas suitable for gas-engines.

This generator enables oils of an inferior value to that suitable for ordinary petroleum engines to be used.

The generator, Fig. 28, consists of a sheet-iron drum lined with fireclay, forming a slow combustion chamber, in the centre of which is placed an iron retort. The inner part is heated by the slow combustion coke stove surrounding the annular space. The petroleum oil, allowed to trickle down the central tube, is first vaporised and partly gasified on its passage down, and, on reaching the bottom of the tube, this vapour is passed up the annular space between the central pipe and the inner side of the retort. This chamber is highly heated, and the vapour is converted into permanent gas by contact with the inside heated surfaces.

The suspended sediment falls into an inner grate, and can be removed from the bottom of the retort. The gas is led off at the top of annular chamber towards the right, and cleansed in the usual way, by passing through a condenser and purifier consisting of oxide of iron to the gasholder.

By means of this small oil-gas plant, oil of an inferior value, as de-hydrated petroleum at 3½d. per gallon, is made into gas fit for use in gas-engines.

Enriched Producer Gas.

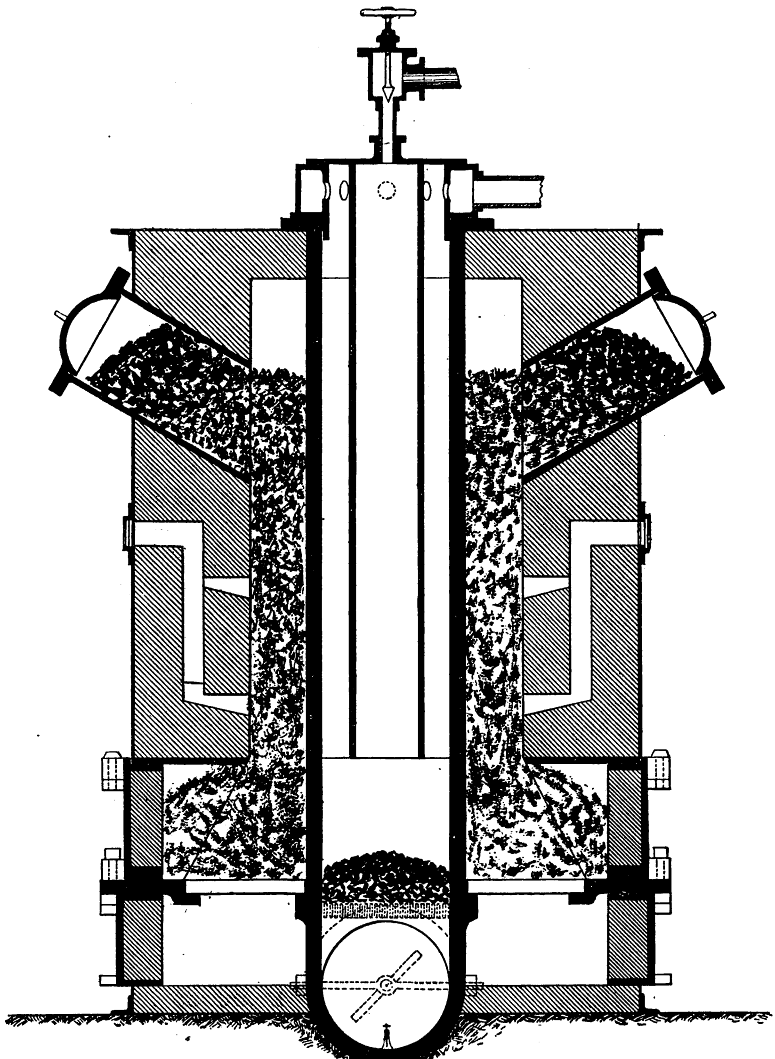
Mr. Thwaite has also devised a larger producer, in which ordinary producer gas is enriched by means of oil. Fig. 29 (p. 1015) shows the general arrangement of the complete plant for enriching water-gas. Fig. 30 (p. 1016) is a vertical section of the producer in the large gas-generating plant at the Southall Gas Works of the Brentford Gas Corporation.

The action depends upon the decomposition of hydro-carbons by heat, by which the oil is converted into a gas of fixed quality.

The cycle of actions is novel. There are two generator vessels (Fig. 30) working alternately. Both vessels are charged with coke or anthracite coal, which is fed into them by an ingenious and automatic contrivance, that not only elevates the fuel to the full height, but transmits it to the generators, into which it is fed regularly and certainly, and without loss of combustible gas.

Above the fuel in each generator, during one part of the operation, some of the gases generated in the vessels are burned, and the products of combustion are drawn through the flue connecting the two vessels into the second

FIG. 28.



THWAITE RETORT OIL-GAS GENERATOR.

vessel, through the incandescent fuel of which the products of combustion (H_2O and CO_2) are drawn, being split up in their descent into (H and CO) hydrogen and carbon-monoxide, which can be collected in a separate holder or utilised for diluting the results of the volatilization of the petroleum.

The cycle is alternately in one direction and then in another, the direction being reversed by automatic reversal valves.

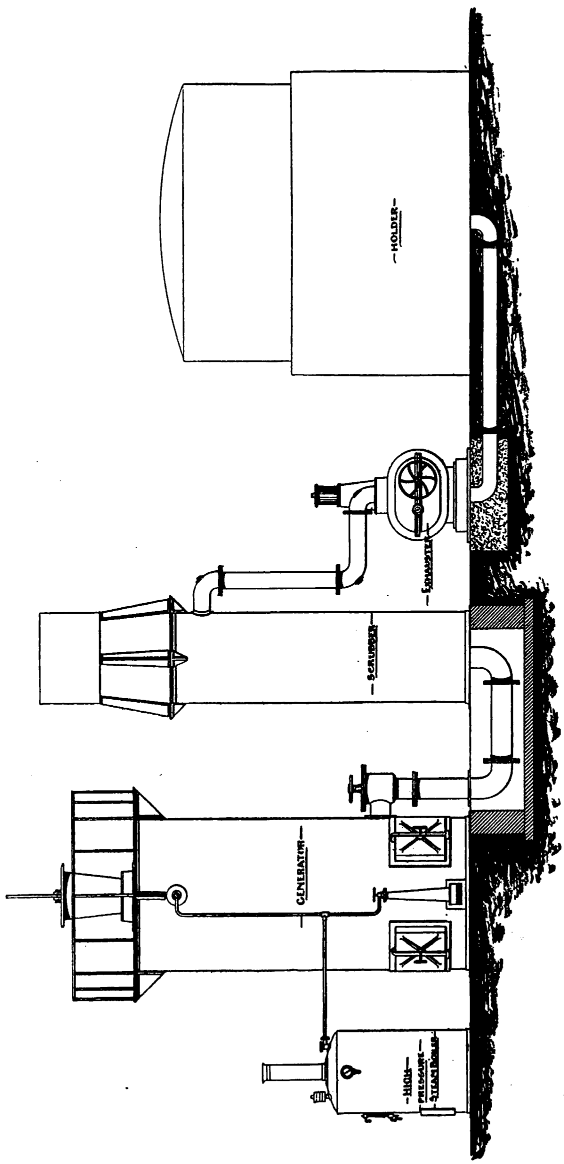
After four reversals, the air is shut off, the oil is then sprayed in by a steam injector (Fig. 29), and is immediately volatilised in one of the chambers; the oil-gas, along

with the steam, flows through the connecting flue (Fig. 30) into the second vessel; and, in descending through the incandescent fuel in second generator, the oil-gas is decomposed by heat into the higher of the hydrocarbon series, and is converted into a gas of a permanent character.

The permanent re-arrangement is the result of a catalytic combination of the hydrocarbon vapour with the steam at a certain temperature, depending upon the temperature of the steam, and the specific gravity of the injected oil.

The injection of oil continues in the Thwaite

FIG. 29.



ENRICHED WATER-GAS PLANT.—ELEVATION.

generator as long as the temperature of the fuel does not fall below a certain limit. When this limit is approached the oil is shut off, and the cycle already described is repeated.

In this way, the crudest oil is made available for use, and the gas leaves the generator in a fairly permanent condition.

The gas thus produced has about the same calorific value as ordinary lighting gas, and can, therefore, be used in a gas-engine, without necessitating any modification of its values.

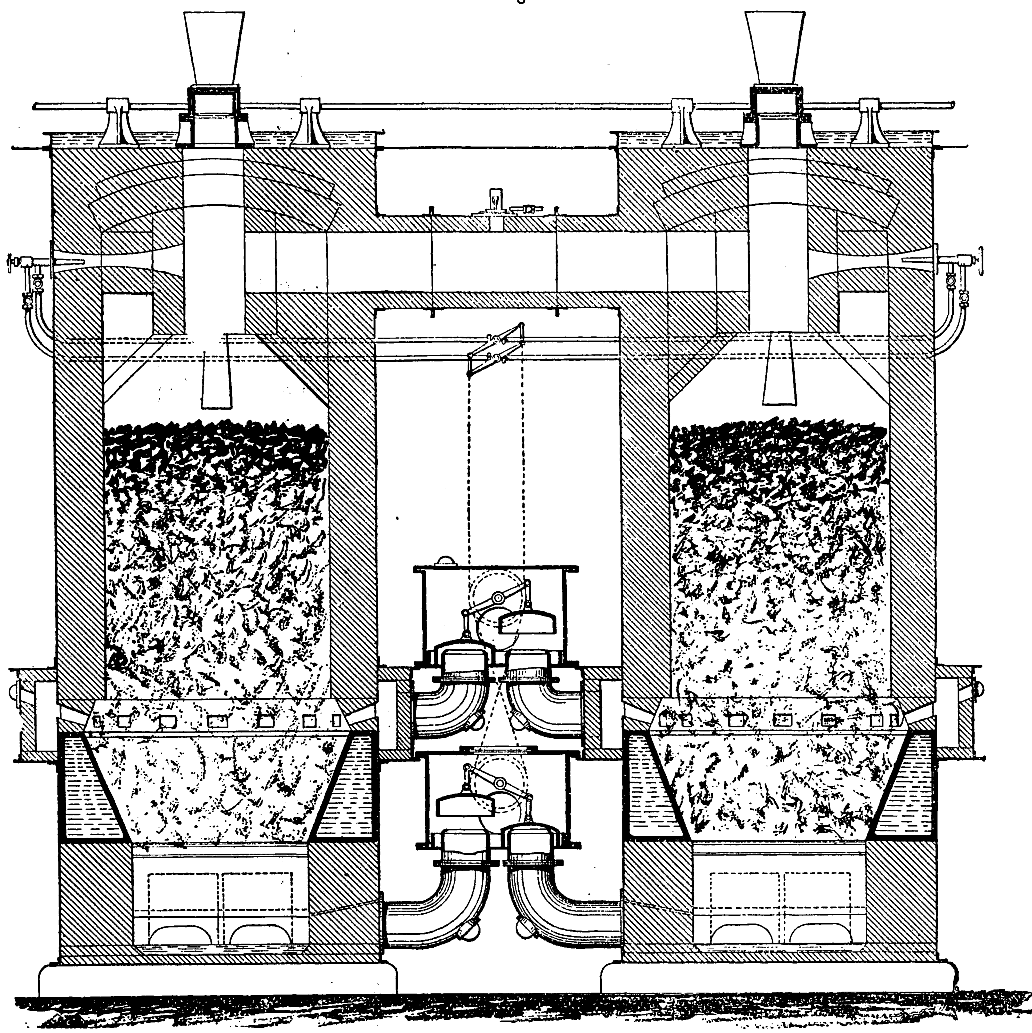
The proportions of valves and parts in the gas-engine are usually such as adapt it for work with ordinary lighting gas.

Consequently, for either very rich or poor gas the valves have to be specially designed. Moreover, for a given power or output, with a very weak gas, such as Dowson gas of only one fourth the calorific value of lighting gas, the moving parts of the engine must be made much larger, and the loss in friction thereby increased, giving a lower mechanical efficiency.

Now, by this apparatus you may enrich the producer-gas up to the same calorific power as ordinary coal-gas.

A simple expedient is adopted to show ordinary workmen the lighting value of the gas as it is produced. A standard light of known value, and under a given pressure, is maintained alongside another jet of the gas that is being produced, and under a like pressure the relative heights of the two flames show the relative values of the gases at a glance.

FIG. 30.



THWAITE GAS GENERATOR.

The cost of enriched generator-gas of a given calorific power mainly depends on the price of the oil. In fact, of the whole cost of working, about 95 per cent. will go for fuel, 3 per cent. anthracite or coke, and 2 per cent. labour.

With anthracite as the solid fuel, the labour and tar troubles are materially reduced, and the efficiency of the fuel is much increased. Taking crude petroleum at 50s. per ton at the works, the cost of the enriched gas, equal to ordinary London coal-gas in lighting and heating power, comes out not less than 1s. 8d. per

1,000 cubic feet, independently of the cost of condensation, purification, and the expenses incident to such work. With the price of oil at 70s. a ton, the cost of the gas, of the same calorific value, will run to 2s. 6d. a 1,000 cubic feet. This enriched gas is about equal to ordinary 16 candle London lighting gas. The calorific value may be taken at 630 British thermal units per cubic foot.

Continuous Producer.

With this intermittent and alternative or reversible method of working, the composition of the gas must vary considerably; and Mr. Thwaite employs a continuous working system which is a modification of the other. In this arrangement one of the two cupolas is charged with anthracite, and the second cupola with open refractory material.

The generator-gas is burned in the chamber over the fuel, and also over the refractory material. The effect of this combustion is to raise the temperature of the refractory material to a bright cherry-red heat, ample for gasifying the oil, which is injected, under high pressure, into the heated chamber above the fuel, where it is vaporised. This evaporation is assisted by breaking up the oil, by means of the steam-jet used in spraying it.

The oil-spray is immediately vaporised, and, passing into the second cupola, is brought into contact with the heated refractory surfaces.

There is decomposition due to the reaction between the steam and heated hydro-carbon vapours, resulting in the production of a fixed or true gas. This action proceeds as long as the temperature is maintained. The oil-gas is generated simultaneously with the producer, or carbonic oxide gas—the latter diluting or reducing the calorific value.

In order to renew the temperature of the vaporising and fixing cupola, all that is necessary is to shut off the oil supply and open the air valves, so that the generator-gas is continually produced and burned to raise the temperature to the required degree.

With regard to economy for gas-engines, such enriching plant can only be used where you have very cheap oil as waste product available, and the gas is made on a large scale.

Cost of Working.

Although, as we have already seen, the combined efficiency of the oil-gas producer and gas-engine, as a heat-engine, is 50 per cent. higher than the steam-boiler and steam-engine, yet from a practical point of view we must reckon the cost of the fuel employed. The price of best Welsh coal is 24s. a ton, that is 0·1286d. per lb., so that the cost of fuel alone, per effective horse-power, for a large condensing steam-engine, using 2 lb. per hour, comes to ·26d., and for a small non-condensing steam-engine, using 6 lb. to 8 lb. per hour, cost 0·77d. to 1·03d. At the very lowest price oil is 2½d. per gallon of 8·5 lb., that is 0·3d. per lb., or more than double the cost of coals in this country. Obviously, then, the gas-engine is working at a great disadvantage as regards the price of oil-gas supply, but, even under these circumstances, the cost of working compares favourably with the average run of small non-condensing steam-engines.

Further, there are other considerations, which change the question entirely, or, at least, materially affects the comparison. The first cost and attendance are practically the same in both cases. For a small plant, one unskilled labourer or stoker is quite sufficient to look after the gas-engine and gas-producer.

Besides, after making gas continuously for a whole day, the attendant can have that gas stored in a gas-holder, and afterwards used directly to supply the engine without any trouble. Herein lies the great advantage of the gas-engine, wherever intermittent work is required. You can start the gas-engine at a moment's notice. Not so in the case of the steam-boiler and engine. In order to be ready for work, you must first of all get up steam in the boiler, and, for intermittent running, keep the boiler standing in steam—an expensive proceeding—and, with fires banked, yet even then you cannot avoid waste of steam or extra expense of fuel, when the work to be done is not continuous.

Furthermore oil-gas may be very useful for other purposes, such as heating and lighting.

We thus see there are substantial advantages in favour of the use of oil wherever it is cheap and plentiful, also in manufactories where you have a waste-product in the form of some kind of inexpensive oil that may be readily converted into gas.

For large powers the practical point is the low price of coal hereabouts, except during long strikes, and there is the great advantage of the perfect mechanism of the steam-engine, which runs smoothly and steadily, without any objectionable noise or smell.

Consequently, it appears that in this country, taking the present prices of coal and oil, the

large oil-gas plant and gas-engine cannot compete with the large condensing steam-engine and high pressure steam boiler; however handy and useful the small oil-gas plant may be in cases where coal is very high in price, and the work to be done intermittent.

In isolated places, and generally for small powers, the favourite prime mover will be the oil-engine that uses the common refined petroleum oils, to be had in abundance in every part of the country, because this engine is self-contained, works steadily and satisfactorily, with efficiency about double that of the oil-gas engine system, and superior to any steam-engine of the same power.

Miscellaneous.

CULTIVATION AND PRODUCTION OF COFFEE IN COSTA RICA.

Coffee plantations are chiefly cultivated in the vicinity of the capital, San José, at an altitude of 3,711 feet above sea level; in the province of Cartago, 4,633 feet above sea level; in Heredia, 3,655 feet above sea level; and Alajuela, 2,950 feet above sea level. A recent bulletin of the Bureau of the American Republics states that the largest coffee plantations are to be found in Heredia and in Santo Domingo. "Coffea Arabica" is the species grown in Costa Rica. There is also the "Grecia" coffee, but it is not very much cultivated. Some years ago Liberia coffee was introduced, and its cultivation appears to extend throughout the Republic. When the shrub (Coffea Arabica) is four years old, it has reached the full amount of production; it is then from six to eight feet high. It blossoms in April or May. The berry in the first year of its existence is a dark green colour, changing to a yellowish red, and finally to crimson. A great amount of labour is necessary to keep the coffee plantations free from weeds. Workmen are provided with large sharp shovels, with which they cut down the weeds, and heap loose earth round the trunk to form low ridges. This earth serves to cover the weeds and hasten their decomposition. This operation is called, in the country, *aporca*, and is effected in May or June. During the winter months the operation is reversed. The ridges built up in summer are now spread out between the rows of coffee. This operation is called *desaporca*. The *aporca* is again done before harvesting, in order to have the ground clean, and to facilitate the picking up of the berries that fall during the harvesting. Finally, the *desaporca* is again done after the crop has been harvested. Once a year, as a general rule, the plantation is ploughed, but only on one side of the rows, the other side being left for ploughing in the next year. In order to prevent the coffee flowers from being damaged by the sun's rays, experience has proved that the coffee tree should not be left without shade. For that purpose banana trees are planted between each third or fourth row of coffee trees. Besides bananas, many other trees are planted, which, with their large branches, cover a great deal of ground. Special species of acacia have proved to be beneficial in the plantations of coffee, or *cafetales*. *Poró juiquininquil*, &c., are grown among the shrubs, and some of them bear excellent fruit crops. Pruning is performed in order to let air and light circulate freely among the trees, to facilitate their development, and to obtain the largest possible crop. The planters in Costa Rica are not all agreed as to the best method of pruning. Some think that no branches other than those which are dead should be cut off, while the majority know that great benefits may be derived from a judicious pruning, and that the future crops may be vastly increased. The latter not only cut off the dead branches, but also those that appear to be half dead. When the trees are five or six feet high, they are topped, to prevent them from growing out of reach. This operation is performed by pinching off the two new leaves which form the top of the tree. It has been calculated that, in 1890, on 8,130 coffee estates there were 26,558,251 coffee shrubs. Each tree produces from one to two pounds, and frequently five or six pounds of coffee in *oro*, that is to say, ready for the market. Harvesting begins as soon as the berries are quite ripe, usually from November to February. The gathering of coffee is done by men, women, and children. The harvesting is performed methodically. A man who takes care of the crops assigns to the *cafeteros* those trees which must be picked first. In the evening an ox-cart is driven to the places where the picking is going on, in order to load the coffee gathered during the day. As soon as the coffee is loaded, it is immediately taken to the factory and thrown into a brick tank, which is larger or smaller according to the size of the plantation. It is large enough to hold as much coffee as can be picked in a day. Water is allowed to run in, in sufficient quantities to thoroughly cover the berries, which are left to soak for a short time. The berries are then taken from this tank to the pulper, through a channel, by means of water. Pulping consists in the separation of the beans from the pulp in which they were enveloped by means of a machine composed of an iron cylinder covered by a sheet of copper, having its surface toothed. At a convenient distance from this cylinder there is a piece of iron, placed in such a way that no bean can pass through this part of the machine and the cylinder without being squeezed. The bruised beans pass through the teeth of the machine while the pulp falls to one side. The pulp is carefully gathered and piled up in heaps, where it ferments. Finally, it is used as a manure for coffee and sugar-cane. The beans coming from the pulper are covered by a

parchment-like membrane and saccharine matter. If these are not removed from the berries, they will dry easily or rot. For this reason a special fermentation is needed. Drying is one of the most important operations in the preparation of coffee, because if it were allowed to become too dry, it would lose weight, and present an unattractive appearance. If too wet it would become mouldy and spoil. The beans coming from the tank are spread on the *patios*, or drying floors, to a depth of two or three inches, and are constantly turned over with light rakes. When the beans are perfectly dry, which is known by the fact that they can not be dented with the finger-nail, and that they crack between the teeth instead of tearing, they are fit to be stored or peeled. Peeling, or hulling, has for its object the removal of the parchment skin that is still adherent to the dry bean. To perform this operation the beans are thrown into a circular basin with a broad channel or groove. Two or more wooden or stone wheels, moved by oxen or water power, run in this circular groove, which has been filled half or three-quarters' full with dry beans. In the centre of the basin, or *trilla*, an axis is fastened to the ground. From this two or more horizontal bars serve to move the wheels, which are kept running until all the dry beans have been separated from their parchment cover. From the *trilla*, coffee husks and dust are put into bags and thrown into a winnowing machine. The husks are blown out by the current of air, while the coffee, falling down, passes through different sieves. The uppermost sieves have round holes, which allow the sand, smaller beans, and stones to pass through, while the larger beans are retained. The second sieve has holes small enough to permit the sand and very small gravel to get through, but not the perfect coffee beans which fall by the front part of the machine. There is yet another skin, called "silver skin," that must be removed. The operation is the same as for peeling, but with lighter wooden wheels. The coffee, as it comes from the hulling machine, goes to the *pulidor*, for it requires to be separated into various sizes for market. The machine which performs this classification is called *clasificador*. It is composed of a long, horizontal cylindrical sieve, formed of galvanised or steel wire, divided into sections of different meshes. A very strong brush of the same length, but smaller, lies against, and turns with, the cylindrical sieve so as to prevent the coffee from choking the meshes. The *clasificador* is run by hand or by hydraulic power. In the first section the sand and dust fall down; in the next the small and broken beans; in the third large beans; while in the last the largest beans are delivered. The coffee from each division is gathered apart, and forms the first, second, or third class, and pea berry, or *caracolillo*. After this mechanical sorting, coffee passes through women's hands, who pick up and separate light coffee, foreign seeds, &c. This work is done on tables made specially for this purpose, and the coffee coming from these tables is put up in sacks, containing about 130 lbs. each, and shipped. The quantity of coffee exported in 1890 was about 34,000,000 lbs., valued at over $9,000,000. This is an increase in four years of 15,000,000 lbs.

THE BALATA TRADE OF PARAMARIBO.

Under the name of "balata," a substance resembling gutta-percha has been before the public more or less since 1859. Little, at first, was known about it, or of the plant from whence it was obtained, except that it belonged to the natural order *Sapotaceæ*, which furnishes true gutta-percha. More attention was, however, drawn to the substance during the year of the London International Exhibition in 1862, where it formed one of the exhibits from Demerara. Sir William Holmes, who was commissioner for the colony, sent a sample of balata to the Society of Arts in 1864, which is recorded in the *Journal* for February 26th of that year, vol. xii, p. 229; and again more fully in the same volume, p. 245, for March 4th. In this communication the tree is decribed as *Sapota Mulleri*, Miq. In the following year, namely 1865, some 20,000 lbs. were imported into England, since which time it was largely used by the India-rubber, Gutta-percha, and Telegraph Works Company at Silvertown, but it was given up on account of its becoming brittle and cracking upon exposure, so that a year or two back the imports to this country had dwindled down to fifty tons annually. Another impulse seems, however, to be given to this industry, for in a recently issued report from the Foreign-office on the trade of Paramaribo, it is stated that "the balata industry has just begun to attract attention, the exports in 1891 amounting to £11,949, as against £7,951 in 1890; and in 1892 there will be a large increase. It was only last year that this industry was considered of sufficient importance to be regulated by special laws. Laws have now been made, and, consequently, the balata industry has attracted foreign capital and labour, English, American, and local firms having taken over leases of land to prospect for, and to bleed the bullet tree. The new regulations require that every one taking out a concession shall deposit as security 1,000 florins (or £83 6s. 8d.), and guarantee that they will begin to work with a stipulated number of labourers within four months of the date of the grant; that competent overseers are employed to supervise the work and see that the trees are not destroyed. All the balata collected has to be delivered at the Government depôts to be weighed, and a tax of 10 cents Dutch (equal to 2d. per lb. or kilo) is collected on it. Large grants of land have been made to various persons to prospect for bullet trees, but there are still large tracts of unexplored forest available. The Government makes no charge for the land granted for exploration, but collects a tax on the products. The largest part of the

balata produced in this colony is exported to Demerara, and thence to England. The United States, as yet, take but a small share of it." It is now known that the tree which furnishes balata is the *Mimusops globosa*, Gaertn.

CHICAGO EXHIBITION BUILDINGS.

The correspondent of *The Times*, in the second (17th Oct.) of a series of articles on the Exhibition, gives the following account of the present condition of the ground and buildings:—

The first impression made upon entering the Exposition enclosure and going about the grounds is that, with few exceptions, the great buildings are practically completed, the whole aspect of the Fair showing a state of preparation much further advanced than one would have supposed possible so far ahead of the opening day, which is seven months off—May 1, 1893. The desire to have the buildings completed in time for the dedication this month has been the incentive for this remarkable progress. A cold winter may come, to retard outdoor work, but they are now away beyond risk of delay from this cause. Some of the interiors are not yet entirely finished, and scaffolding enfolds one or two of the great domes. Outside decoration and painting is everywhere going on, with a very large amount of the statuary and other outside ornamentation already in place. A week sees marvellous progress in this sort of work, most of the artistic adornments being ready. I hear that all the building contractors are substautially up to time in the progress of the buildings, most of which are ready for the reception of goods.

The preparation of the grounds has made great progress. The lagoons, canals, islands, and most of the bridges are finished; and also many of the lawns and footways. The terraces and walls adjoining these waterways seem to be almost entirely completed. The plaza or grand court, being still largely used for railroads and wagon-roads fetching in materials, has not yet had its surface arranged. The protecting wall, paved shore, and broad footwalk out in front of the Manufactures Building on the lake front, stretching from the steamboat pier northward to the British House, making a grand curved esplanade, which is one of the attractive features, are entirely finished. The terrace between the building and this footwalk, which is to be composed of lawns, kiosks, &c., has not yet been arranged. Flower beds are everywhere ready, but the flowers will no be set out until spring. Thousands of people go every day to the grounds and watch with interest the progress of the work. On fine Sundays as many as 15,000 have entered the gates. They pay a shilling a-piece, this source having already brought in £20,000, an item which will largely increase.

The United States battleship, which has been built up from the bottom of the lake behind a protecting breakwater at the upper pier, is practically finished, and looks lifelike from all along the lake front, its turrets, stacks, and towers rising above the deck, and long guns pointing over bow and stern. Here will be made the Government naval display. Almost alongside stands the solid-looking "Victoria House" of the British Section, occupying an admirable place in the foreground of the Exposition, overlooking the lake, whose waters reach within a few feet of its doors. The first storey is up and building progress is rapid. It is an English half-timber house of the 16th century, yellow terra-cotta being largely used in the lower storey with red-brick facing and mullioned windows. The upper portion will be of half-timber construction, with over-hanging and projecting gables. The building being in full view from all sides, each façade is treated architecturally. The plan forms three sides of a quadrangle, with the open side next the lake, enclosed by a raised terrace with balustrade. The interior will furnish offices for the British Section, and the principal rooms will be fitted up with wall panelling and elaborate ceilings, like some of the best English country houses. This house is a feature that is distinctly unique, and it attracts great attention. Colonel Grover, of the Royal Engineers, is here superintending the construction for the Commission.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, OCT. 31...Farmers' Club, Salisbury-square Hotel, Fleet-street, E.C., 4 p.m. Mr. Dugdale, "County Council Plans for Providing Technical Instruction in Agriculture."

TUESDAY, NOV. 1...Zoological, 3, Hanover-square, W., 8½ p.m. 1. Mr. Oldfield Thomas, "Mammals from Nyassaland." 2. Mr. R. Lydekker, "Zeuglodont and other Cetacean Remains from the Tertiaries of the Caucasus." 3. Prof. F. Jeffrey Bell, "Description of a Remarkable New Species of *Cidaris* from Mauritius."

WEDNESDAY, NOV. 2 ... Public Analysts (At the HOUSE OF THE SOCIETY OF ARTS) 8 p.m. 1. Mr. C. W. Heaton, "Note on a sample of poor, but undoubtedly genuine Milk." 2. Mr. Alfred Smetham, "Composition of an abnormal sample of Milk." 3. Dr. Bernard Dyer, "Note on a case of abnormal Milk."

Entomological, 11, Chandos-street, W. 7 p.m. 1. Mr. Charles J. Gahan, "Additions to the Longicornia of Mexico and Central America, with Notes on some previously recorded species." 2. Mr. W. E. L. Distant, "Contributions to a knowledge of the Homopterous Family Fulgoridæ." 3. Mr. Edward B. Poulton, "Further Observations upon Lepidoptera, 1888—1892." 4. Mr. Oswald H. Latter, "The Secretion of Potassium-Hydrate by *Dicranura vinula*, and the emergence of the imago from the Cocoon." 5. Messrs. Henry J. Elwes and James Edwards, "A revision of the genus *Ypthima*, principally founded on the form of the genitalia in the male sex."

THURSDAY, NOV. 3...Linnean, Burlington-house, W., 8 p.m. Rev. Professor Henslow, "A Theoretical Origin of Endogens through an aquatic habit."

Ladies' Sanitary Association, 22, Berners-street, W., 3 p.m. Miss Homersham, "Nursing the Sick."

FRIDAY, NOV. 4...Geologists' Association, University College, W.C., 8 p.m. Conversazione.

Journal of the Society of Arts.

No. 2,085. Vol. XL.

FRIDAY, NOVEMBER 4, 1892.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

ARRANGEMENTS FOR THE SESSION.

The First Meeting of the One Hundred and Thirty-ninth Session of the Society will be held on Wednesday, the 16th November, when the Opening Address will be delivered by Sir Richard Webster, Q.C., M.P., Chairman of the Council. Previous to Christmas, there will be four Ordinary Meetings, in addition to the Opening Meeting. The following arrangements have been made:—

November 16.—Opening Address by Sir Richard Webster, Q.C., M.P., Chairman of the Council.

Papers for which dates have not yet been fixed:—

"The Chicago Exhibition, 1893." By James Dredge.

"Transatlantic Steamships." By Prof. Francis Elgar, LL.D.

"The Disposal of the Dead." By F. Seymour Haden, F.R.C.S.

"The Copper Resources of the United States." By James Douglas.

"The Detection and Estimation of Small Proportions of Inflammable Gas or Vapour in the Air." By Prof. Frank Clowes, D.Sc.

"The Purification of the Air Supply to Public Buildings and Dwellings." By William Key.

"The Utilisation of Niagara." By Prof. George Forbes, F.R.S.

"Pottery Glazes: their Classification and Decorative Value in Ceramic Design." By Wilton P. Rix.

"The Chemical Technology of Oil Boiling, with a Description of a New Process for the Preparation of Drying Oils, and an Oil Varnish." By Prof. W. Noel Hartley, F.R.S.

"The Mining Industries of South Africa." By Bennett H. Brough.

"Ten Years of Progress in India." By Sir William Wilson Hunter, K.C.S.I., C.I.E., LL.D.

"Australasia as a Field for Anglo-Indian Colonisation." By Sir Edward N. C. Braddon, K.C.M.G., Agent-General for Tasmania.

"Indian Manufactures." By Sir Juland Danvers, K.C.S.I., late Public Works Secretary, India-office.

"Caste and Occupation at the last Census of India." By Jervoise Athelstane Baines, I.C.S., Imperial Census Commissioner for India.

"Mexico, Past and Present." By Edward J. Howell.

"Newfoundland." By Cecil Fane.

"New Zealand." By W. B. Percival, Agent-General for New Zealand.

Indian Section.

The meetings of this Section will take place on the following Thursday Afternoons, at Half-past Four o'clock:—

January 19; February 16; March 9; April 6, 27; May 11.

Foreign and Colonial Section.

The meetings of this Section will take place on the following Tuesdays, at Half-past Four or Eight o'clock:—

January 17; February 28; March 21; April 2, 16.

Applied Art Section.

The meetings of this Section will take place on the following Tuesday Evenings, at Eight o'clock:—

January 24; February 7, 21; March 14; April 11; May 9.

Cantor Lectures.

The following courses of Cantor lectures will be delivered on Monday Evenings, at Eight o'clock:—

Prof. Vivian Lewes, "The Generation of Light from Coal Gas." Four Lectures.
November 21, 28; December 5, 12.

Dr. J. A. Fleming, "The Practical Measurement of Alternating Electric Currents." Four Lectures.
January 30; February 6, 13, 20.

Prof. W. Chandler Roberts-Austen, C.B., F.R.S., "Alloys." Three Lectures.
March 6, 13, 20.

Lewis Foreman Day, "Some Masters of Ornament." Four Lectures.
April 10, 17, 24; May 1.

C. Harrison Townsend, F.R.I.B.A., "The History and Practice of Mosaics." Two Lectures.
May 8, 15.

Howard Lectures.

A Special Course of Six Lectures, under the

Howard Bequest, will be delivered on the following Friday Evenings, at Eight o'clock:—

PROF. W. CAWTHORNE UNWIN, F.R.S., "The Development and Transmission of Power from Central Stations."

January 13, 20, 27; February 3, 10, 17.

JUVENILE LECTURES.

Two lectures, suitable for a juvenile audience, will be delivered on Wednesday evenings, January 4 and 11, 1893, at 7 p.m.

Chicago Exhibition, 1893.

MEETING OF THE ROYAL COMMISSION.

A meeting of the Royal Commission was held on Thursday, 3rd November. Present: Sir Richard Webster, Q.C., M.P., Chairman; Sir George Birdwood, K.C.I.E., C.S.I., M.D., Sir Edward Braddon, K.C.M.G., Major-Gen. Sir Owen Tudor Burne, K.C.S.I., C.I.E., Michael Carteighe, R. Brudenell Carter, F.R.C.S., Francis Cobb, Prof. James Dewar, M.A., F.R.S., Major-General J. F. D. Donnelly, C.B., Sir Henry Doulton, James Dredge, Sir Douglas Galton, K.C.B., F.R.S., Walter H. Harris, A. B. W. Kennedy, F.R.S., C. Malcolm Kennedy, C.B., J. Fletcher Moulton, Q.C., F.R.S., John O'Connor, Prof. W. Chandler Roberts-Austen, C.B., F.R.S., Sir Owen Roberts, M.A., with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

EXECUTIVE COMMITTEE.

A meeting of the Executive Committee was held on Monday, 31st October. Present: Sir Frederick Bramwell, Bart., D.C.L., F.R.S., in the chair; Sir Frederick Abel, K.C.B., D.C.L., D.Sc., F.R.S., Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D., R. Brudenell Carter, F.R.C.S., Sir George Hayter Chubb, B. Francis Cobb, Sir Henry Doulton, James Dredge, Sir Douglas Galton, K.C.B., D.C.L., F.R.S., Sir Owen Roberts, M.A., D.C.L., F.S.A., with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

ELECTRICAL COMMITTEE.

A meeting of the Committee on Electricity was held on Thursday, 27th October. Present: W. H. Preece, F.R.S., in the chair; Prof. W. Grylls Adams, M.A., F.R.S., Prof. W. E. Ayrton, F.R.S., Major-General E. R. Festing, F.R.S., Prof. George Forbes, M.A., F.R.S., J. E. H. Gordon, Prof. David E. Hughes, F.R.S., W. M. Mordey, Mark Robinson, Alexander Siemens, C. E. Spagnoletti, Major-General C. E. Webber, C.B., James Wimshurst, with Sir Henry Trueman Wood, M.A., Secretary to the Royal Commission.

Proceedings of the Society.

CANTOR LECTURES.

USES OF PETROLEUM IN PRIME MOVERS.

BY PROFESSOR W. ROBINSON, M.E.,
Assoc. M.Inst. C.E., University College, Nottingham.

Lecture IV.—Delivered March 21, 1892.

OIL-FUEL FOR STEAM BOILERS.

The fourth use of oil in prime motors is as fuel instead of coal or wood to raise steam for the production of mechanical energy. Perhaps the use of oil as fuel dates further back than any other application of it that we have considered. Rock-oil is frequently referred to in the Bible and other ancient historic records. Job said, "the rock poured me out rivers of oil;" and the spies sent by Moses into the land of Canaan found amongst other good things oil flowing from the rock, which was doubtless used to give both light and heat from the earliest times.

You are well aware that hitherto by far the most extensive use of the valuable products of petroleum, with flashing point from 73° to about 150° Fahr., has been for lighting purposes.

Now, besides the intermediate oils, considered in our last lecture, there are valuable heavy oils used for lubrication, whilst the still heavier cheap oils, available for liquid fuel, are mainly obtained (1) as residue or waste products from the mineral-oil industry, and (2) as liquid hydrocarbons recovered from coal-fed blast furnaces, coke-ovens, and gas-producers, known as blast furnace oil, creosote, and common tar-oils. These cheap oils, or heavy waste hydrocarbon products, cannot be easily converted into gas of a fixed character by direct volatilisation, because the gas formed by heating these liquids in a closed vessel at a high temperature, rapidly condenses again

into its original liquid state, when cooled and subjected to pressure. What then is to be done with these products? You will, I think, hold with the poet—

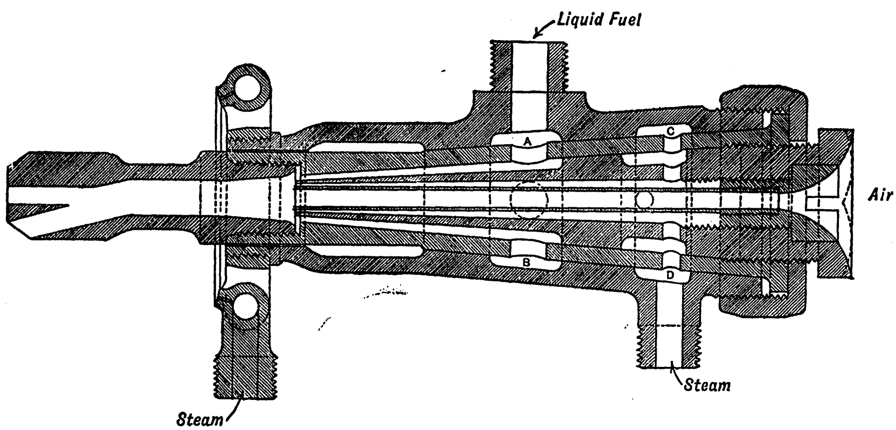
> "That not one drop should be destroyed,
> Or cast as rubbish to the void."

In fact, if you bury the tar, a troublesome waste product that is formed from oil-gas making, it will appear again where least expected, as it did at Stratford in the water mains when rejected from the Great Eastern Oil-gas Works. Therefore, to get rid of such oils effectually, the best way of all is to utilise them as liquid fuel for steam raising, and by this means take advantage of the great improvements which have been made in steam-engines during the last half-century.

Methods of Burning Liquid Fuel.

The simplest method is that adopted by Mr. Ludwig Nobel, at Baku, in burning astatki, the petroleum refuse for steam generating purposes under stationary boilers, by means of "trough burners" like that I hold in my hand. These shallow troughs are arranged in a series one above the other, exposing a large surface, so that the oil trickles or flows down from one stage to the other, and is thus vaporised, ignited, and finally the whole mass is completely burned. With this system of trough burners under a steam-boiler, a practical evaporation of 14½ lbs. of water per pound of petroleum refuse is obtained, whereas a spraying arrangement gives an evaporation of 12 lbs. with this astatki, whilst coal in the same boiler gives an evaporation of 7 lbs. to 8 lbs. of water per pound of fuel.

Fig. 31.



Holden's Injector Burner.

However, the most common and practical method of burning liquid fuel is to spray it into a specially prepared combustion chamber by a jet of superheated steam, through an injector which draws in the air supply at the same time. The oil is thus heated and broken up into the finest spray by the steam, and thoroughly vaporised in the furnace, where it is also mixed with the air, which supplies the oxygen for combustion.

A most important essential is the lining of the furnace or combustion chamber inside with fire-clay or brickwork, to act as an accumulator of heat and keep up a constant high temperature for complete combustion. To this end the fire-bars are usually covered with a layer of fire-brick and fuel, kept incandescent, and the oil is sprayed towards the fire-brick wall or lining. Sometimes hot air is drawn in by the injector and admixed with the oil and superheated steam, causing perfect atomising of the oil.

Holden's Method of Oil-firing.

Take, for example, the system of burning liquid fuel used by Mr. James Holden, locomotive superintendent of the Great Eastern Railway.

Fig. 31 shows a section of the spray-injector (actual injector shown and explained), so arranged that the liquid fuel is allowed to enter at the top and flow down around the passage, A B. The steam enters by C D, and is guided towards the nozzle through the annular passage between the oil-fuel outside and the central tube for the incoming air.

The parts are so proportioned that the liquid fuel is well heated and broken up into fine spray as it is drawn in by means of the steam jet. An auxiliary and entirely independent supply of steam is introduced by the hollow ring surrounding the orifice, and issues through a number of holes converging towards the nozzle of the injector, so that the steam jets from the ring play across the issuing jet of liquid fuel already atomised into spray by the central steam jet and bar in the nozzle of the orifice. The liquid is thus divided into the finest spray, vaporised by the heat, and mixed with a large supply of air drawn in through the central orifice at the back end. This supply of air can be varied by the steam inducing it to get the right amount of air for perfect combustion. The ring supply of steam breaks up the main central jet, so that the whole fuel burns with a flat intense lambent flame, not sharp nor directed like that of a blow-pipe.

The central part of the injector proper is screwed into the casing to facilitate removal, if blocked or damaged on a journey, and to clear away any obstructions without having to shut off either steam or fuel, although the steam blowing through the nozzle keeps it clean.

A modification has been made in these injectors, fitted on the latest express locomotives. The central steam-jet has been slightly altered to form an air injector, and the central cone has communication by means of a flexible hose with the main train pipe of the automatic vacuum brake, so that the air may not be drawn in from the surrounding space merely. The steam used, therefore, in the ordinary injector to spray the liquid fuel is further utilised in creating a vacuum available for purposes other than brake power.

Experience shows that superheated steam is much more economical than wet steam for injection.

The sectional elevation, Fig. 32 (p. 1025), shows the whole firing arrangement on the passenger tank locomotives. There is an oil-tank, F, supplied with oil through a sieve, or strainer, to prevent heavy particles in the oil, which flows along the pipe, D, into the injector, B, and is forced by the steam jet, A, into the open space above the firebars. There may be a coil of steam piping fixed in the tank, F, to heat up the oil in very cold, frosty weather. The firebox is fitted with a fire-brick bridge, towards which the jet is directed, and the bars of the grate are covered with a very thin layer of incandescent fuel, consisting of coal and cinders, mixed with chalk or lime, which keeps up the temperature, and is not merely for burning purposes. The coal burns slowly away, and is renewed to retain an incandescent base on the fire-bars, sufficient, with the fire-brick bridge, to accumulate the heat, and keep the temperature high enough for the decomposition of the oil in the presence of steam, and for the various reactions resulting in the gasifying and complete combustion of the oil.

These express engines can be run with coal without requiring any alteration to the furnace, a point of great importance in countries where the price of oil is high or fluctuating. In fact, coal can be used in an engine at one time, and the next run the liquid fuel. The oil used by Mr. Holden is a mixture of two parts of *coal tar* with one of *green oil*, just to thin it down, the cost being about 1½d. a gallon, or 25s. per ton.

Hydrocarbon refuse, oil-gas tar, creosote, and furnace oils are also used, and one ton of this is found to be nearly equal to two tons of steam coal; but all are inferior to either crude petroleum or petroleum refuse, as, on account of their greater weight, they require more steam for spraying, as well as being inferior in calorific value. At present, however, the price of petroleum refuse is against its adoption in this country.

On the Great Eastern Railway, Mr. Haldane finds that, using oil on an express engine, the consumption of fuels for one month's running has been—

	Per mile run.
Liquid fuel	12·2 lb.
Coal and coke	11·0 lb.
Total	23·2 lb.

including lighting fires and working two systems of continuous brake constantly, viz., Westinghouse for Great Eastern Railway trains, and vacuum for foreign trains.

The consumption of coal on nine engines of the same class, doing similar work, but *not* always working vacuum brakes, averages 34 lb. per mile.

This system of liquid fuel firing has been adopted on the Great Western Railway in the Argentine Republic, where the copious oil deposits are being developed. Fig. 33 (p. 1025) shows to the right an end view of the eight coupled tank locomotives fitted with the oil-firing apparatus. To the left of the same drawing (Fig. 33) is shown the ingenious arrange-

FIG. 32.

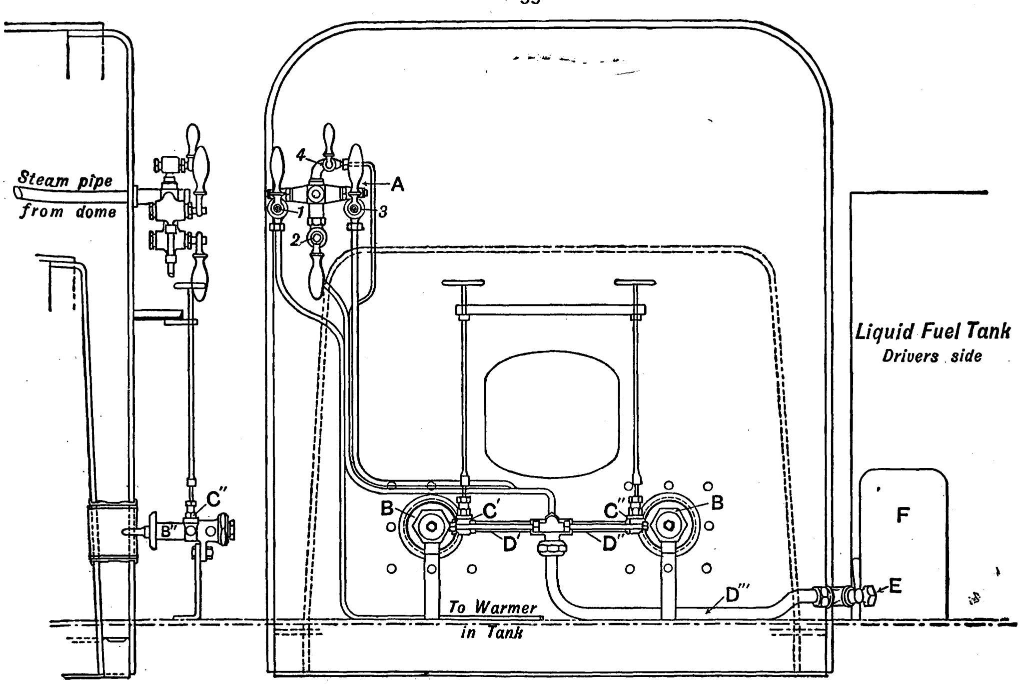
FIG. 33.



OIL-TANK LOCOMOTIVE.

ment for staying the boiler at the point where the injector is fitted. At the top is seen the pipe from the dome conveying superheated steam to the injector. Dry steam gives much more complete combustion than wet steam saturated with moisture, which tends to dull and blacken the fires. In fact, by closing the tap leading to the ring jets I instantly stopped complete combustion, and sent a cloud of smoke up the chimney which on board might be used to signal orders.

On this line the consumption of coal on an ordinary engine is 33 lb. per mile run; but on a liquid-fuel burning engine, fitted similar to above, the consumption is 10lb. of oil and 12lb. of coal and wood, making the total 22 lb. per mile. I need hardly point out that the saving here in favour of liquid fuel is considerable, when coal is put down at £4 per ton and oil costs 48s. per 2,071 lb., the cost of fuel per train mile being 14·18d. and 8·19d. respectively. If each engine runs 18,000 miles per annum, the difference in cost of fuel alone is £450 in favour of the engine burning oil, coal, and wood. At the same time, if these engines were altered to burn oil only, precluding the use of coal, the railway company would soon have to pay more for the oil, the wells being in the hands of a native company. As it is, the engines are equally serviceable with coal as with oil.

The comparative results came out somewhat similar on the Tralee and Dingle Railway, Ireland, where Holden's apparatus is fitted on some of the engines. Taking an average train, the consumption of coal alone on the round trip, Tralee to Dingle, not including steam raising, was 27 cwt., at a cost of 1s. 2d. per cwt. With coal and creosote oil, and a certain amount of broken limestone, the consumption of coal was 4 cwt., and of oil 95 gallons, at 2½d., or just 1½ gallons to the mile. The saving effected with coal and oil is thus 7s. a trip. The results work out average consumption of coal 54 lb. per mile, whereas on the liquid-fuel engine, coal 8 lb. and creosote-oil 18 lb., makes the total consumption of fuels 26 lb. per mile. Here I should mention that this railway is over a mountainous country, with inclines of 1 in 30 for lengths over 3 miles. The excessive fuel consumption is due to the heavy grades, new locomotives, &c. The liquid fuel can be shut off on all the down grades, thus greatly economising the fuels. In this case the automatic vacuum brake is worked as already mentioned, probably saving the equivalent of 3 lb. of coal per mile.

Holden's injector, with liquid fuel firing, arranged as shown in Fig. 34 (p. 1027), in the steam ferry-boat *Middlesex*, on the Thames, gives satisfactory results. The fuel used is a mixture of two parts of coal-tar and one of green oil, o thin it down.

The mixture of coal-tar and green oil costs about 1½d. per gallon, or 25s. per ton. Hydrocarbon refuse, oil gas-tar, creosote and furnace oils are also used, and one ton of this is found to be nearly equal to two tons of steam coal, but all are inferior to either crude petroleum or petroleum refuse; as, on account of their greater weight, they require more steam for spraying, as well as being inferior in calorific value. At present, however, the price of petroleum is against its adoption in this country.

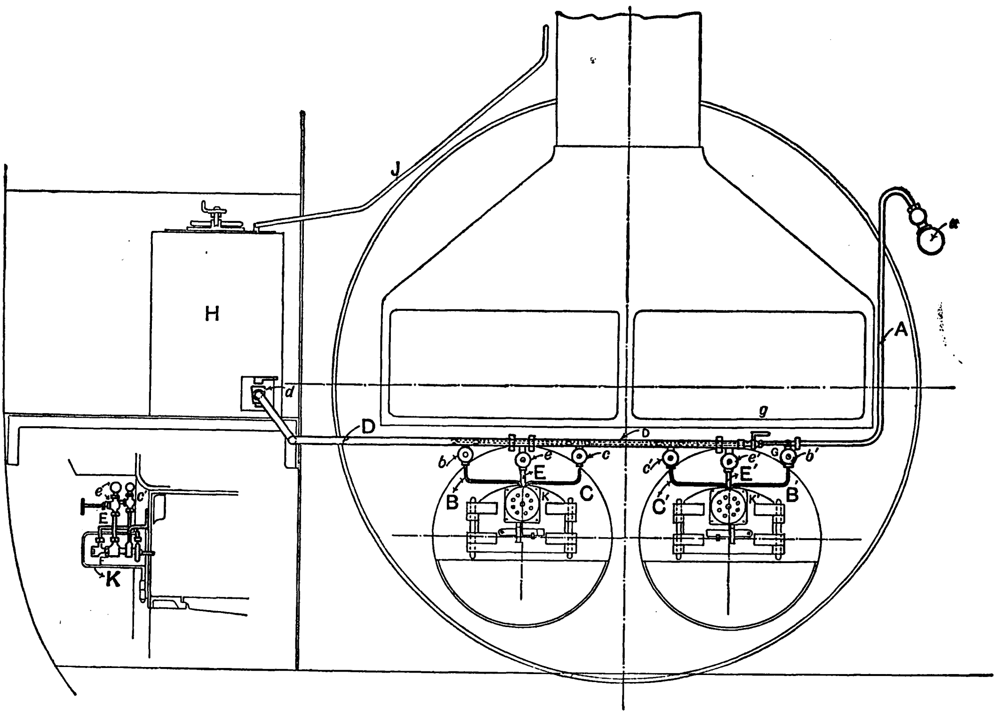
Blast-furnace oil is used to fire stationary boilers in various places throughout the United Kingdom.

Injectors.

Many modifications of these injectors have been proposed to atomise these heavy liquids into spray for burning in the furnace. Here is Thwaite's injector (Fig. 35, p. 1027), which is rifled so as to give the liquid a spiral motion, and thereby mixed the sprayed oil and steam more intimately with the air drawn in through the injector. Again, this injector may be used with an auxiliary hot-air supply by a forced blast, as in the torpedo boat arrangement, Fig. 36 (p. 1027). The hot-air blast aids in the vaporisation of the oil, giving more perfect combustion.

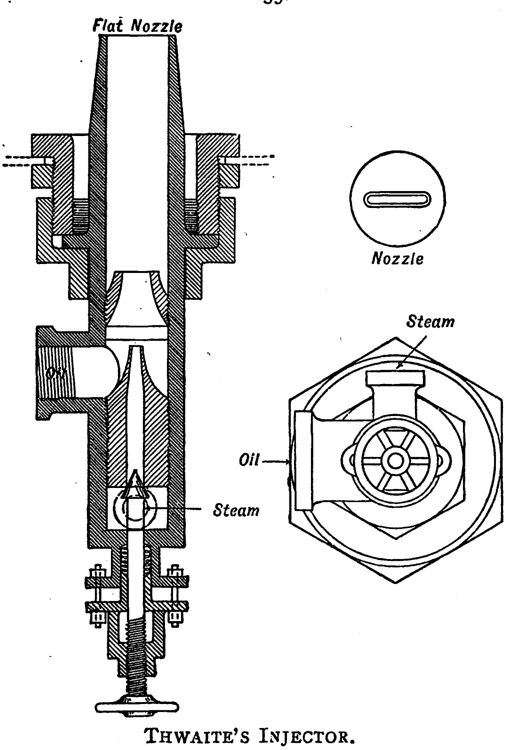
The air-blast can be adjusted to a nicety by the annular nozzle at the one end of the large drum or trunk, Fig. 37 (p. 1028), which you see here on the table. Mr. Thwaite, by this means, uses a minimum quantity of steam. The blast of air comes down the large tube, and the oil is sprayed by steam down below (Fig. 37), using the injector shown in section, Fig. 35. Only enough steam is admitted to spray the oil; the blast of air does the rest. This air-blower, combined with oil-spray injected by steam (Fig. 37), when applied to the furnace or combustion-chamber with fire-brick wall, as in Fig. 36, can be made to give complete combustion. The idea of vaporising the oil-spray is carried still further, as shown by the wall diagram, in which the spray does not pass directly into the fire-box, but first into a red-hot drum, where the oil is converted into fixed oil-gas before being mixed with the air-blast and burned.

FIG. 34.



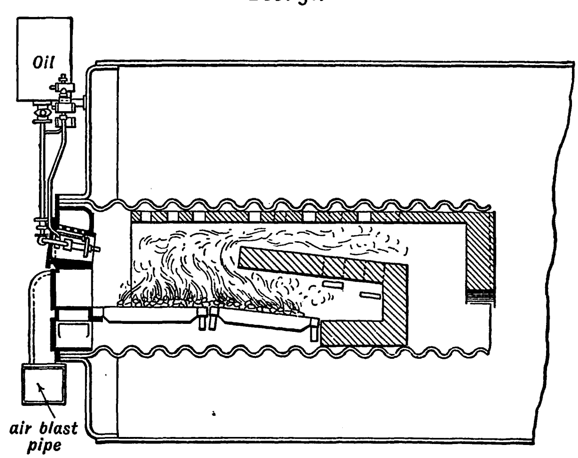
OIL-FIRING IN STEAM FERRY "MIDDLESEX."

FIG. 35.



THWAITE'S INJECTOR.

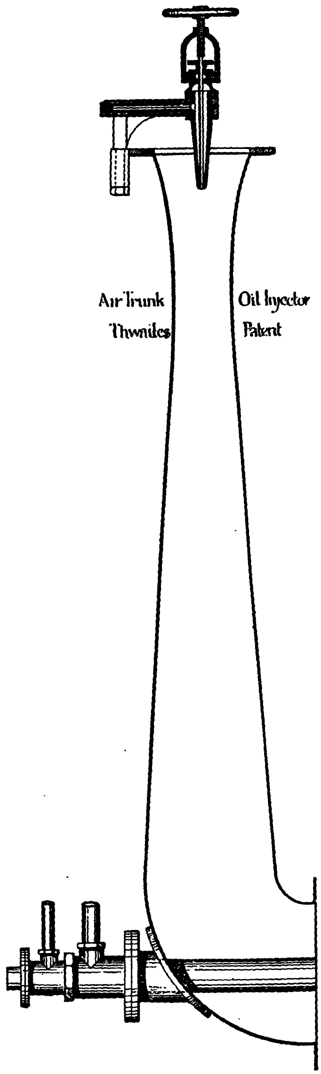
FIG. 36.



OIL-FIRING IN TORPEDO BOAT.

One trouble with most of these injectors is the noise produced by the high-pressure steam passing in. The noise is lessened in the Bray-Smith injector, which you see here, by this large hollow drum at the end. Air is drawn in through these holes in the drum to atomise the oil, whilst the rods across the end of the

FIG. 37.



AIR-BLOWER, WITH SPRAY-INJECTOR.

drum break up the oil-jet still further, and the oil is burned with a diffused, lambent flame, and not the objectionable, blow-pipe flame, which played against one particular part of the boiler-plate or fire-rick.

The most complete and successful system of employing petroleum refuse as fuel in steam boilers and locomotives has been worked out by Mr. Thomas Urquhart, on the Grazi and Tsaritsin Railway, in South-east Russia.* In this locality petroleum refuse, or astatki, is plentiful, and costs 13s. 7d. per ton, whilst the price of coal is 27s. per ton. Since 1884, he has had 143 locomotives under his superintendence, fired with petroleum refuse, besides fifty stationary boilers and several furnaces. It certainly appears that these nine years' experience of the system has shown a notable economy to result from using the heavy astatki, or petroleum refuse, as fuel. In ordinary locomotive practice an evaporation of $12\frac{1}{4}$ lbs. of water is obtained per lb. of petroleum refuse, and the highest actual evaporation 14 lb. of water per lb. of fuel at an effective pressure of 125 lb. per square inch from feed water at 60° Fahr. This result was obtained in a perfectly clean locomotive boiler, with new solid-drawn copper tubes ·079 inches thick and $2\frac{1}{8}$ inches diameter. Again the average consumption of *coal* in eight-wheeled coupled locomotives throughout the year 1882 was 79·98 lb. per engine mile, as compared with the average 40·47 lb. of *petroleum refuse* per engine mile during 1887. Also in special trials of the eight-wheeled engines, the result per ton mile was that forty-five tons of petroleum refuse were equivalent to 100 tons of anthracite, being a reduction of 55 per cent. in weight of fuel. Mr. Urquhart states that these comparisons were made with the greatest care possible, with engines in first-class order, showing the highest efficiency in locomotive practice. He has no hesitation in saying, that "with a locomotive in first-class order, and in the hands of a skilful driver, fifty tons of petroleum refuse are equal to 100 tons of first-class coal."

CALORIFIC VALUE OF LIQUID FUEL.

We must guard against exaggeration as to the calorific power of oil fuel, and, in making our estimate, keep in view the actual conditions that obtain in practice.

From the careful and elaborate experimental researches of Messrs. Fauvre and Silbermann, Dr. Andrews, and others, we know the quantity of heat obtained by the complete combustion of 1 lb. of solid *carbon*, when burned in pure oxygen in a calorimeter surrounded with cold water; and also the heat generated by burning 1 lb. of *gaseous hydrogen* under similar conditions. Then assuming, from the ultimate chemical composition of a fuel, that it is

* "Proceedings Inst. Mech. Engineers," 1889, p. 36.

made up of solid carbon and gaseous hydrogen, mixed loosely together in certain proportions, we may make a rough estimate of the heating value of the fuel, by calculating the heat given out by these constituents burning separately. Here we entirely ignore the obvious fact, that the amount of heat generated by the combustion of a fuel depends not only upon its physical state, but also upon its proximate chemical constitution, which may be wholly unknown. Moreover, it is well known that numerous hydrocarbons, having different properties, are made up of the same proportions of carbon and hydrogen, and yet give out different amounts of heat in burning, because of the heat spent in the internal work of tearing the ultimate particles apart where the carbon and hydrogen are more tightly held together in the more stable substances. In the simple case of pure carbon, the quantity of heat evolved, in burning the different varieties of carbon to form carbonic acid, changes with the density. Favre and Silbermann found the following values for the calorific power:—

	Pound-Centigrade Heat Units.	Pound-Fahr. British Thermal Units.
Carbon of wood charcoal....	8,080·0	14,544
Gas retort carbon (denser) ..	8,047·3	14,485
Natural graphite	7,796·6	14,034
Diamond	7,770·1	13,986

Notwithstanding this variation, the value generally taken for the carbon in liquid and solid fuel alike is that of wood charcoal, although the calorific power of carbon vapour is 11,214 calories, or 20,185 British thermal units.

Again, a similar error is made in calculating the calorific power of hydrogen in various hydrocarbons as if it were in the separate gaseous state in the liquid fuel, which we know is not the case. Then gaseous hydrogen is burned in pure oxygen to form steam, and in the calorimeter there is reckoned not merely the heat generated during the combustion, but that evolved in cooling down the steam to the boiling point, also in condensing the steam and subsequent cooling of the condensed steam down to the ordinary temperature of the atmosphere (59° or 60° Fahr.), and the sum of all these quantities of heat is called the calorific power of hydrogen.

Now, when burning a fuel containing hydrogen in the ordinary furnace, we do not condense the steam and cool the water formed to 60° Fahr. Consequently, we cannot expect to find the total heat value of hydrogen realised. In the same way, when carbon is burned to form carbonic acid, the heat evolved in simply cooling this gas is reckoned as part of the heating power of the carbon. In the experiments of Favre and Silbermann only very small quantities of charcoal, about 38 grains, were burned at a time, and a variable proportion, sometimes 30 per cent., of carbonic oxide was found among the products, showing incomplete combustion or reduction of carbonic acid gas formed, and thus necessitating corrections in order to arrive at the total heat that should be evolved in the complete combustion of the solid carbon with oxygen. These conditions do not closely agree with the physical state of carbon in liquid hydrocarbons, which are readily decomposed in the presence of high pressure steam, yielding gaseous hydrocarbons, especially compounds like olefiant gas, having a high heating power, with deposit of solid carbon. Marsh gas, CH_4, is found, by experiment, to develop 2,672 heat-units per pound less, whilst olefines give out more heat than the ordinary calculation would indicate.

It would, therefore, appear better, in dealing with petroleum oils as fuel, to gain some idea of the proximate chemical constitution of an oil, of the constituent fractions or gases into which it is most likely to be split up by heat as in fractional distillation or in the furnace, and to base the estimate of heating power as that of the gases produced therefrom. Thus mineral oils yield a large proportion of olefiant gas and marsh gas.

When burning solid fuel, it is necessary to introduce into the ordinary furnaces about twice the amount of air required to furnish the oxygen for combustion. Part of the generated heat is spent in raising the temperature of the excess air or nitrogen. In the case of liquids, less surplus air is required, and gases are still more favourable for perfect furnace conditions.

Bearing in mind the uncertainty about the calculation of the calorific values of these oils, founded on the ultimate chemical composition given from analysis, we shall proceed to estimate the heating value of a sample or two in the ordinary way.

According to calorimetric experiments, the total amount of heat that can be obtained at ordinary atmospheric temperature, 60° Fahr.,

by the combustion of the fuel and subsequent cooling of the burnt products, including condensation of steam formed, is from

	British Thermal Units.
1 lb. of pure carbon,	about 14,500
1 lb. of hydrogen,	about 62,000

If, then, C and H stand for the per-centages of carbon and hydrogen present in 1 lb. of the fuel, its total heat of combustion in calorimeter, when the steam produced is condensed, is given by the sum of the products

$$14{,}500 \times C + 62{,}000 \times H.$$

All the other constituents are neglected.

Now, since the heating value of hydrogen is nearly 4·28 times that of carbon, we may write the simple approximation to the heating power thus :—

$$\left.\begin{array}{r}\text{Calorimetric value}\\ \text{1 lb. of fuel.}\end{array}\right\} \begin{array}{l}\text{British thermal units.}\\ = 14{,}500\,(C + 4{\cdot}28\,H.)\end{array}$$

Professor Rankine pointed out that a convenient thermal unit for evaporation is the heat required to evaporate 1 lb. of water under the mean atmospheric pressure of 14·7 lb. per square inch, the water being supplied to the boiler at 212° Fahr., or 100° C., the boiling point of water. This unit of evaporation is the quantity of heat required to evaporate 1 lb. of water at 212° Fahr., that is, the latent heat of evaporation, which is 966 British thermal units. The *evaporative power* of a fuel is the number of pounds of water that 1 lb. of the fuel can evaporate at mean atmospheric pressure from and at 212° Fahr.

If we start with water at the ordinary temperature, say 62° Fahr., and heat 1 lb. of it up through 150° to the boiling point 212° Fahr., we should require 150 British thermal units to the boiling point, and then 966 British thermal units would be spent in the evaporation of the 1 lb. of water at 212° ; so that, altogether, the amount of heat required to heat up and change 1 lb. of water from 62° Fahr. into 1 lb. of steam at 212°, under the mean atmospheric pressure of 14·7 lbs. per square inch, is 150 by 966, or 1,116 British thermal units.

Blast-furnace Oil

We shall now calculate the heating value of blast-furnace (coke oven) oil. Two samples of this oil, of specific gravity 920, analysed by Mr. Alfred Allen, of Sheffield, were found to have the following elementary composition :—

	1st Sample.	2nd Sample.	Average.
Carbon	83·380	83·900	83·640
Hydrogen	10·530	10·650	10·590
Sulphur	0·087	0·088	0·0875
Oxygen, &c., by difference......	6·003	5·872	5·9385
	100·000	100·000	100·2560

The oil was further tested by Mr. William Thompson, of Manchester, who estimated its relative calorimetric value by saturating a piece of pumice stone with a known weight of the oil, placing it in the crucible of his water calorimeter, and allowing it to burn slowly in his water calorimeter supplied with oxygen. The burnt products bubbled up through the water, and so raised its temperature. After allowing for loss of heat by radiation, &c., the result obtained for the actual heating or calorimetric value was 16,080 British thermal units, equivalent to an evaporation from and at 212° Fahr. of $\frac{16080}{966}$ or $16\frac{2}{3}$ lb. of water per 1 lb. of oil, provided the whole of the actual heating power was available *above* 212° Fahr., which does not appear to be the case.

In order to calculate this heating value of the oil by our formula, we use the average composition, and have calorimetric value per lb. of fuel = 14,500 (0·8364 + 4·28 × 0·1059) = 18,705 thermal units. Since 1 lb. of hydrogen, when burned, forms 9 lbs. of steam for every pound of oil, the hydrogen 0·1059 lb. will form 0·1059 × 9, or ·9531 lb. of steam. This steam, if not allowed to condense at 212°, and cool to 62° F., will carry off 966 + 150 = 1,116 thermal units per 1 lb., and, therefore, the steam formed, if not condensed, will carry away 0·9531 × 1116 = 1,064 thermal units.

Further, every 1 lb. of carbon forms $3\frac{2}{3}$ lbs. of carbonic acid gas (CO_2), so that for every pound of oil, the 0 8364 lb. of carbon forms 0·8364 × 3·6 = 3·067 lb. of CO_2.

If not cooled below 212° F. to the temperature of cold water, 62° F.—that is, through 150° F.—part of the heat will not be available above 212° F., and must be deducted below 212° F. The specific heat of carbonic acid gas is 0·2164, therefore the quantity of heat lost in not cooling this product below 212° F. is 3·067 × ·2164 × 150 = 99·56, or nearly 100 thermal units.

Thus, for the steam and carbonic acid

formed, we deduct 1,064 + 100 thermal units from the total calorimetric value, 18,705 − 1,164, leaving 17,541 as the first approximation to the effecting heating power above 212° Fahr.

Again, in actual burning of this oil, there must be at least sufficient air introduced to furnish the necessary oxygen for combustion, and, at the same time, the nitrogen of the air comes in with the O, and has to be heated, so that it also takes up part of the heat evolved to raise it above 212° Fahr.

Every 1 lb. of hydrogen requires 34·8 lb. of air, giving 26·8 lb. of nitrogen; so that ·1059 lb. of hydrogen requires 26·8 × 0·1059 = 2·84 lb. of nitrogen; also, every 1 lb. of carbon needs 11·6 lb. air, giving 8·94 lb. nitrogen; then ·8364 lb. carbon needs 8·94 × ·8364 = 7·48 lb. of nitrogen.

Altogether, 2·84 + 7·48 = 10·32 lb. of nitrogen is introduced of specific heat ·244, and raised in temperature from 62° to 212°; that is, 150°; and therefore takes away heat = 10 × ·244 × 150 = 366 thermal units.

Further deducting this quantity of heat from heating value 17,541 − 366, leaving available above 212° Fahr., the effective calorific value = 17,175 thermal units, that is considerably in excess of the actual calorimetric estimation.

In order to calculate the evaporative power, at any given temperature, of the heat of combustion, we must thus deduct from the total calorimetric value, as found by above formula, the total heat that would be evolved by all the products in cooling below that particular temperature to 62° Fahr. Then the remaining available thermal units, divided by the amount necessary to evaporate 1 lb. of water at that temperature, will give the evaporative power, assuming a perfect boiler.

For instance, suppose for the moment that the above effective calorific value, 17,175 thermal units, were available above 281° Fahr., the temperature at which steam is generated, under a pressnre of 50 lb. per square inch, we are given that the total heat required to produce steam at 50 lb. per square inch (at 281° Fahr.) from water at 62° Fahr. is 1,137 thermal units. If the water is supplied at 212° Fahr., then the heat required will be 150 units less, that is, 1,137 − 150 = 987 thermal units.

Therefore, the greatest possible amount of water that could be evaporated with the given effective heat = $\frac{17175}{987}$ = 17·4 lb.

There is always loss of heat in the steam boiler, so let us assume a loss of 30 per cent., efficiency of boiler 70 per cent., that is to say, of the effective heat given by the fuel, the boiler utilises 70 per cent.; then the evaporation comes out 17·4 × 70, or about 12 lb. of steam formed at pressure of 50 lb. per square inch, when feed water is supplied at 212° Fahr. If the boiler efficiency were 75 per cent., then the evaporation would be 17·4 × 75, or 13 lb. of water at 281° Fahr. from 212° Fahr.

As a matter of fact, Dr. Sadler, of Middlesborough, finds, as the result of a large number of trials of creosote oil as fuel in a steam boiler, that 1 lb. of creosote oil evaporates, or converts, 13 lb. of water into steam at 50 lb. per square inch, with water supplied at 212° Fahr. From this we must deduct 5 per cent. of the steam formed, which is used up in supplying steam to the jet of the oil injector, leaving about 12·35 lb. of water evaporated by means of 1 lb. of creosote oil fuel.

In the same boiler he carried out a series of very careful evaporating trials with best Durham steam coal, and the best result obtained was that 1 lb. coal formed 8 lb. of steam, at a pressure of 50 lb. to the square inch, from water supplied at 212°, as compared with over 12 lb. evaporation with creosote under same conditions.

The evaporative power is not alone a sufficient test of the value of a fuel. Liquid fuel has a number of practical advantages in its favour when compared with coal. In fact, a boiler worked with liquid fuel gives fully 10 per cent. more effective power, as there is no clearing or stoking fires, and the firing is uniform and continuous. Whereas, in a boiler fired by hand with coal, the fire doors are continually being opened, admitting cold air. In the case of oil fuel, there is no expense in removing ashes, cleaning of grates, &c. such labour is practically dispensed with. Taking all these advantages into account, Dr. Sadler finds, by experience, that one ton of oil is equal to two tons of coal.

Petroleum Refuse.

In order to compare such calculations with practical results, take the astatki, or petroleum refuse, used by Mr. Urquhart in locomotives in South-east Russia. The chemical composition of petroleum refuse, of specific gravity ·928, is in 1 lb. of oil-carbon ·871, and hydrogen ·117. The calorimetric value per lb. is = 14,500 (0·871 × 4·28 × 0·117) = 19,832 thermal units. For every lb. of oil burned 9, × 0·117 = 1·053 lb. of steam would be formed, which, if not condensed and cooled to 62° Fahr. would

escape and carry off per lb. the latent heat of evaporation at 212°, namely, 966 units, and the heat otherwise evolved in cooling as water, say to 62° Fahr., that is 150 thermals, or a total per lb. of 1,116 thermal units, included in the above calorimetric value. Hence we must deduct from this the heat carried away by the steam $9 \times 0{\cdot}117 \times 1{,}116 = 1{,}175$ thermal units. Neglecting the small loss of heat in the hot carbonic acid formed, also included in the calorimetric value, the effective calorific value of the oil refuse is $19{,}832 - 1{,}175 = 18{,}657$ thermal units. Consequently the evaporative power is $\frac{18657}{966} = 19{\cdot}3$ lb. of water from and at 212° Fahr.

Again, the heat required to form 1 lb. of steam, at pressure of 125 lb. per square inch, from water at 59° or 60° Fahr., is 1,162 thermal units. Therefore, the greatest possible evaporation per lb. of oil refuse under these conditions would be $\frac{18657}{1162} = 16{\cdot}05$ lb. of water. This is with boiler efficiency 100 per cent.

The highest actual evaporation given is 14 lb. per lb. of oil; that is, with a boiler efficiency of 87 per cent., since $16{\cdot}05 \times 87 = 14$.

In ordinary practice, the evaporation of 12½ lb. of water per lb. of oil would indicate a boiler efficiency above 76 per cent.

This calculation can only be very approximate, since the conditions of combustion in the ordinary calorimeter are so very different from the state of things in the combustion chamber of the locomotive.

Table VI. gives the composition of heavy refuse, suitable for liquid fuel. Although the above examples prove conclusively that 1 lb. of oil fuel can evaporate much more water than 1 lb. of coal, still 1d. worth of oil has not in it the calorific power equal to that of 1d. worth of coal, under ordinary working conditions. Hence, if in this country you have a hydrocarbon produced in the ordinary process of manufacture as a residual product, like "dead oil," then you may use such refuse as a liquid fuel with decided economy.

Advantages of Oil-fuel.

In considering the relative value of two fuels, the evaporative or calorific power must not be taken alone. There are important advantages attending the use of petroleum as fuel, instead of coals, on board ship, which we cannot afford to overlook. Thus there is absence of smoke, the oil fires are completely under control, and more perfect combustion is ensured without hard labour being imposed on human beings called stokers, coal trimmers, and the like. Fire-grates do not need cleaning of clinker as when coal is used. Boiler tubes do not need sweeping so often. Besides, the carrying capacity of ships is reduced for any given power, and any large warship in the fleet is enabled to take liquid fuel aboard easily and quickly at sea without loss. Besides, the absence of coal-dust, ashes, and cinders is very important for the machinery in high speed vessels, as well as for comfort of passengers.

The disadvantages are (1) danger of explosion from inflammable vapour collecting, as in the case of coal dust. The oil-tank ought on no account to be examined by a naked flame or light. It is of vast importance to

have some kind of safety lamp, such as that invented by my colleague, Professor Frank Clowes, D.Sc., by means of which the slightest tendency to an inflammable mixture is immediately detected. (2) Cost of oil compared with coal, and the difficulty of having an assured supply of oil in large quantities at a reasonable price.

[*To be continued.*]

Miscellaneous.

RUSSIAN SALT INDUSTRY.

The following particulars respecting the salt deposits of the Russian Empire and the salt industry in that country are obtained by the *Board of Trade Journal* from the *Viestnik Finançoff*. It is stated that the country possesses sufficient salt, not only for its own use, but for the whole European consumption for many centuries:—

"The annual consumption of salt in Europe, including Russia, is estimated at 5,625,000 tons, and yet a comparatively small section of the Iletz mines—by no means the chief salt mines of Russia—is computed to contain 1,607,000,000 of tons of rock salt. As the principal centres of the industry are situated in the southern and eastern extremities of the empire, where, until recently, there were few transport facilities, Russia had always been compelled to draw her salt, to a certain extent, from abroad; and even now she imports about 16,000 tons annually, although no longer so dependent on foreign supplies since the discovery of rich deposits in Yekaterinburg, the extension of the railway system, and the regulation of tariff rates.

"Since 1818, both the State and private capitalists have been engaged in the salt industry in Russia; in the latter case, the product had to be sold to the State, or else—a fixed duty having been paid—it could be sold without further restriction. In this way arose competition between the State and private enterprise, and the Government, without prohibiting the import of salt, imposed a Customs' duty equivalent to the internal salt tax. It was not till 1862 that the Government saw the wisdom of abandoning such a system, and, retiring from the enterprise, simply levied the tax. As a result, the production of salt rose from 418,000 tons, in 1861, to 723,000 tons in 1862.

"The salt tax brought the Government about 10,000,000 roubles per annum, and in 1881 this was sacrificed, and the Customs' duty also reduced for the benefit of the agricultural, cattle-rearing, and manufacturing communities. As a consequence, the salt consumption rose 80 per cent. between 1881 and 1890.

"The production of rock salt has increased 358 per cent. since 1870; that of lake salt, 240 per cent.; and that of brine salt, 98 per cent. On the whole, the production has increased 192 per cent. within the last 20 years.

"By far the greater part of Russia's salt is obtained from the lakes. The great lowland lying between the Caspian Sea and the Sea of Aral, and which was once the bottom of an immense sea connected with the Arctic Ocean on the north, and the Black Sea on the south, contains several thousands of salt lakes, which, roughly, may be divided into three categories: those formed by the alkalisation of the soil, those formed by inundations, and those fed by salt springs. The richest of the salt lakes is that of Elton, in the government of Astrakhan, and about 93 miles from the Volga, where salt has been produced from the remotest times. This lake is now, however, entirely superseded by Lake Baskounchak, only about 33 miles from the Volga, and more favourably situated for transport purposes. The importance of Baskounchak was much enhanced by its railway connection, in 1882, with the port of Vladimir, on the Volga.

"Of 147,000 tons of salt produced in 1886 in the government of Astrakhan, Lake Elton produced 94,000 tons. At that time Lake Baskounchak was not being worked. In 1870, the same government produced 103,000 tons, of which Lake Elton contributed 16,300 tons only, and Baskounchak 20,600 tons. Ten years later, Elton produced only 8,400 tons, and Lake Baskounchak 162,000 tons, and now the latter yields more salt than any other place in Russia (16 per cent. of the total production), while Lake Elton is no longer worked.

"Lake Baskounchak has an area of 70 square miles, and is dry during the spring and summer months, when the bed is covered with a layer of salt, consisting of various strata, the first of which is from three to four fathoms thick, being, in its turn, made up of strata consisting of salts of various qualities. The best salt is obtained from the third of these latter strata from the top, and is known as *granitka*. The salt of most frequent formation is called *novosadki;* it is softer than, and often preferred to, the *granitka*.

"The lake salts have varieties of colour as well as of hardness. Some salts are snow-white, others bluish, pink, grey, and black. The dearest is the 'snow-white.'

"The lake is divided into 360 allotments, which are farmed out at rates chargeable on every 1,000 pouds of output, and determined by public tender, according to the position of the allotments. The rates vary between 10 and 30 roubles per 1,000 pouds, or one to three copecks the poud.

"The quarrying, &c., is entrusted by the allotment holders to labourers' 'artels.' The average output per man is about 80 or 100 tons for the season (April to October), for which he gets from 7 to 10 roubles, according to the depth from which the salt is obtained.

"The remaining salt lakes of the Aral Caspian low-

land are scattered along the Caspian coast in the government of Sevastopol, the district of Daghestan, Baku, and the Trans-Caspian, Ural, and Tourgai districts. In all these places, however, the salt industry has a purely local significance.

"Like the shores of the Caspian Sea, the northern coast of the Black Sea is studded with salt lakes, which, though not so rich in salt as the lakes in Astrakhan, yet yield a large quantity.

"A greater expenditure of labour and care is here necessary, as artificial basins have often to be constructed to anticipate the exhaustion of the lakes.

"The labour so expended is, however, compensated for by the favourable geographical situation of the salt factories.

"The salt lakes of the Crimea may be divided into five groups: those of Eupatoria, Perekop, Genichesk, Kertch-Theodosian, and Kinburn group, and the lakes in the vicinity of the railway. The lakes of the Eupatorian group belong partly to the State and private capitalists.

"The State lakes are farmed at charges varying between one and four copecks per poud of the output. The most important of them are the Saksk and Sasyk-Sivash lakes which, together, produced 84,100 tons of salt in 1890. The most important of the private lakes is Kamrat, which produced 11,000 tons in that year. The output of the Perekop lakes is only about 8,000 tons. Of the so-called railway lakes, one, extending to the Taganash station of the Lozovo-Sevastopol line, produces 64,300 tons per annum; another, Lake Chongar, about 56,200 tons, and the whole group about 129,000 tons. The Genichesk and the Kertch-Theodosian and Kinburn groups produce together about 7,000,000 pouds, making 377,000 tons for all the Crimean lakes.

"In point of quantity of output, salt from the springs comes next in importance. The brine either flows spontaneously from natural springs or is pumped from artificial wells and borings. Provided cheap fuel is at hand, this branch of the salt industry is very profitable. The government of Perm is in every way adapted for carrying on this branch of industry with success. It was first started here in the reign of the Tsar John, surnamed 'The Stern.' The brine is here pumped from depths varying between 28 and 90 fathoms. During boring operations on the estates of Count Stroganoff, 11 rock-salt beds, averaging each 20 fathoms of thickness, were encountered, the first at a depth of 73 fathoms.

"The production of salt in Perm in 1890 was 289,000 tons, and was obtained from 66 borings and wells. Most of the works are situated along the banks of the Kama, which affords transport facilities in despatching salt and obtaining fuel. The output of the government of Perm has risen from 179,000 tons in 1881 to 289,000 tons in 1890.

"After Perm comes Kharkoff in the production of salt from brine. Donetz coal is here used exclusively as fuel, and only about half a poud (18 lbs.) of coal is consumed in producing a poud of salt, whereas in the Perm salines, owing, no doubt, to the inferior quality of the coal, 32 cwt. of the latter are required in producing 39 to 43 cwt. of salt.

"The chief brine wells of the Kharkoff government are situated near the town of Slaviansk, where, in 1890, there were 21 establishments at work, producing in all 52,000 tons of salt, or 2,475 tons each, as compared with 19,290 tons in Perm.

"The third place of importance for salines is Bachmut, in the government of Yekaterinoslav, where, in 1890, a single factory turned out 28,200 tons of salt.

"Of the total production of salt in 1890, 81 per cent. came from Bachmut in the government of Yekaterinoslav. Other rock-salt beds of Russia are those of Iletz, Erivan, and Kars, the production of the two latter in 1890 being respectively 12,600 tons and 6,350 tons."

MEETINGS FOR THE ENSUING WEEK.

MONDAY, Nov. 7...Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.
Engineers, Westminster Town-hall, W., 7½ p.m. Mr. W. H. Holttum, "The use of Steel Needles in driving a Tunnel at King's-cross."
Chemical Industry (London Section), Burlington-house, W., 8 p.m. 1. "New Method for the Preparation of Nitrous Oxide." 2. Mr. Watson Smith, "Notes on Schurmann's Reactions." 3. Prof. W. Ramsay and Mr. J. C. Chorley, "Distillation of Wood."
British Architects, 9, Conduit-street, W., 8 p.m. The Opening Address, by J. Macvicar Anderson, President.

TUESDAY, Nov. 8...Civil Engineers, 25, Great George-street, S.W., 8 p.m. Address by the President, Mr. Harrison Hayter.
Photographic, 5A, Pall-mall East, S.W., 8 p.m. 1. Address by the President. 2. Mr. Howard Farmer, "Some remarkable properties of Silver and Gelatine."
Anthropological, 3, Hanover-square, W., 8½ p.m. 1. Mr. E. F. Im Thurn, "Anthropological Uses of the Camera." 2. Mr. H. Ling Roth, "Couvade." 3. Mr. S. E. Peal, "The Morong."
Colonial Inst., Whitehall Rooms, Hotel Metropole, S.W., 8 p.m. Sir Malcolm Fraser, "The Present Condition and Prospects of Western Australia."

WEDNESDAY, Nov. 9...Geological, Burlington-house, W., 8 p.m. 1. Professor M. E. Wadsworth, "A Sketch of the Geology of the Iron, Gold, and Copper Districts of Michigan." 2. Mr. H. M. Becher, "The Gold-quartz Deposits of Pahang (Malay Peninsula)." 3. Mr. F. D. Power, "The Pambula Gold Deposits"

THURSDAY, Nov 10...Electrical Engineers, 25, Great George-street, S.W., 8 p.m. Discussion on Mr. James Swinburne's paper, "The Problems of Commercial Electrolysis."

FRIDAY, Nov. 11...Astronomical, Burlington-house, W., 8 p.m.
Physical, Science Schools, South Kensington, S.W., 5 p.m. Continued Discussion on the papers by Mr. Williams and Mr. Sutherland, "Dimensions of Physical Quantities," and "Molecular Forces."

SATURDAY, Nov. 12...North-East Coast Institute of Engineers and Shipbuilders, The Athenæum, West Hartlepool, 7½ p.m.
Botanic, Inner-circle, Regent's-park, N.W., 3¾ p.m.

Journal of the Society of Arts.

No. 2,086. Vol. XL.

FRIDAY, NOVEMBER 11, 1892.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, London, W.C.

Notices.

ARRANGEMENTS FOR THE SESSION.

The First Meeting of the One Hundred and Thirty-ninth Session of the Society will be held on Wednesday, the 16th November, when the Opening Address will be delivered by Sir RICHARD WEBSTER, Q.C., M.P., Chairman of the Council. Previous to Christmas, there will be four Ordinary Meetings, in addition to the Opening Meeting. The following arrangements have been made:—

ORDINARY MEETINGS.

NOVEMBER 16.—Opening Address by Sir RICHARD WEBSTER, Q.C., M.P., Chairman of the Council.

NOVEMBER 23.—"The Disposal of the Dead." By F. SEYMOUR HADEN, F.R.C.S. DR. G. V. POORE will preside.

NOVEMBER 30.—"The Copper Resources of the United States." By JAMES DOUGLAS.

DECEMBER 7.—"The Chicago Exhibition, 1893." By JAMES DREDGE.

DECEMBER 14.—"The Utilisation of Niagara." By PROF. GEORGE FORBES, F.R.S. SIR RICHARD WEBSTER, Q.C., M.P., will preside.

Papers for which dates have not yet been fixed:—

"Transatlantic Steamships." By PROF. FRANCIS ELGAR, LL.D.

"The Detection and Estimation of Small Proportions of Inflammable Gas or Vapour in the Air." By PROF. FRANK CLOWES, D.Sc.

"The Purification of the Air Supply to Public Buildings and Dwellings." By WILLIAM KEY.

"Pottery Glazes: their Classification and Decorative Value in Ceramic Design." By WILTON P. RIX.

"The Chemical Technology of Oil Boiling, with a Description of a New Process for the Preparation of Drying Oils, and an Oil Varnish." By PROF. W. NOEL HARTLEY, F.R.S.

"The Mining Industries of South Africa." By BENNETT H. BROUGH.

"Ten Years of Progress in India." By SIR WILLIAM WILSON HUNTER, K.C.S.I., C.I.E., LL.D.

"Australasia as a Field for Anglo-Indian Colonisation." By SIR EDWARD N. C. BRADDON, K.C.M.G., Agent-General for Tasmania.

"Indian Manufactures." By SIR JULAND DANVERS, K.C.S.I., late Public Works Secretary, India-office.

"Caste and Occupation at the last Census of India." By JERVOISE ATHELSTANE BAINES, I.C.S., Imperial Census Commissioner for India.

"Mexico, Past and Present." By EDWARD J. HOWELL.

"Newfoundland." By CECIL FANE.

"New Zealand." By W. B. PERCIVAL, Agent-General for New Zealand.

INDIAN SECTION.

The meetings of this Section will take place on the following Thursday Afternoons, at Half-past Four o'clock:—

January 19; February 16; March 9; April 6, 27; May 11.

FOREIGN AND COLONIAL SECTION.

The meetings of this Section will take place on the following Tuesdays, at Half-past Four or Eight o'clock:—

January 17; February 28; March 21; April 2, 16.

APPLIED ART SECTION.

The meetings of this Section will take place on the following Tuesday Evenings, at Eight o'clock:—

January 24; February 7, 21; March 14; April 11; May 9.

CANTOR LECTURES.

The following courses of Cantor lectures will be delivered on Monday Evenings, at Eight o'clock:—

PROF. VIVIAN LEWES, "The Generation of Light from Coal Gas." Four Lectures.

November 21, 28; December 5, 12.

DR. J. A. FLEMING, "The Practical Measurement of Alternating Electric Currents." Four Lectures.

January 30; February 6, 13, 20.

PROF. W. CHANDLER ROBERTS-AUSTEN, C.B., F.R.S., "Alloys." Three Lectures.

March 6, 13, 20.

LEWIS FOREMAN DAY, "Some Masters of Ornament." Four Lectures.

April 10, 17, 24; May 1.

C. HARRISON TOWNSEND, F.R.I.B.A., "The

History and Practice of Mosaics." Two Lectures.

May 8, 15.

HOWARD LECTURES.

A Special Course of Six Lectures, under the Howard Bequest, will be delivered on the following Friday Evenings, at Eight o'clock:—

PROF. W. CAWTHORNE UNWIN, F.R.S., "The Development and Transmission of Power from Central Stations."

January 13, 20, 27; February 3, 10, 17.

JUVENILE LECTURES.

Two lectures, suitable for a juvenile audience, will be delivered on Wednesday evenings, January 4 and 11, 1893, at 7 p.m.

INDIAN SECTION.

A meeting of the Committee of the Section was held on Tuesday, 8th inst., at 4 p.m. Present:—SIR GEORGE BIRDWOOD, K.C.I.E., C.S.I., M.D., LL.D., in the chair, Lionel Ashburner, Major-General Sir Owen Tudor Burne, K.C.S.I., C.I.E., F. C. Danvers, Walter H. Harris, C. M. Kennedy, C.B., Alexander Rogers, Sir Charles Turner, K.C.I.E., Sir Alexander Wilson, W. Martin Wood, with Sir Henry Trueman Wood, Secretary of the Society, and S. Digby, Secretary of he Committee.

The programme of papers to be read during the present Session was discussed.

"OWEN JONES" PRIZES.

This competition was instituted in 1878, by the Council of the Society of Arts, as trustees of the sum of £400, presented to them by the Owen Jones Memorial Committee, being the balance of subscriptions to that fund, upon condition of their expending the interest thereof in prizes to "Students of the School of Art who, in actual competition, produce the best design for Household Furniture, Carpets, Wall-papers and Hangings, Damask, Chintzes, &c., regulated by the principles laid down by Owen Jones." The prizes are awarded on the results of the annual competition of the Science and Art Department.

Six prizes were offered for competition in he present year, each prize consisting of a bound copy of Owen Jones's "Principles of Design," and a Bronze Medal.

The following is a list of the successful candidates:—

Robert Dow, School of Art, Glasgow.—Design for a printed hanging.

Florence Morris, School of Art, Hertford.—Design for a plate.

William Spiers, School of Art, Glasgow.—Design for a hanging.

Ella B. Ginn, School of Art, Hertford.—Design for wall tiles.

Ada Hasleham, School of Art, Cavendish-street, Manchester.—Design for a printed cotton.

Joseph G. Slade, School of Art, Cavendish-street, Manchester.—Design for calico prints.

The next award will be made in 1893, when six prizes will be offered for competition.

Proceedings of the Society.

CANTOR LECTURES.

USES OF PETROLEUM IN PRIME MOVERS.

By PROFESSOR W. ROBINSON, M.E.,
Assoc. M.Inst. C.E., University College, Nottingham.

Lecture IV.—Delivered March 21, 1892.

[*Concluded from p.* 1032.]

OIL STORAGE.

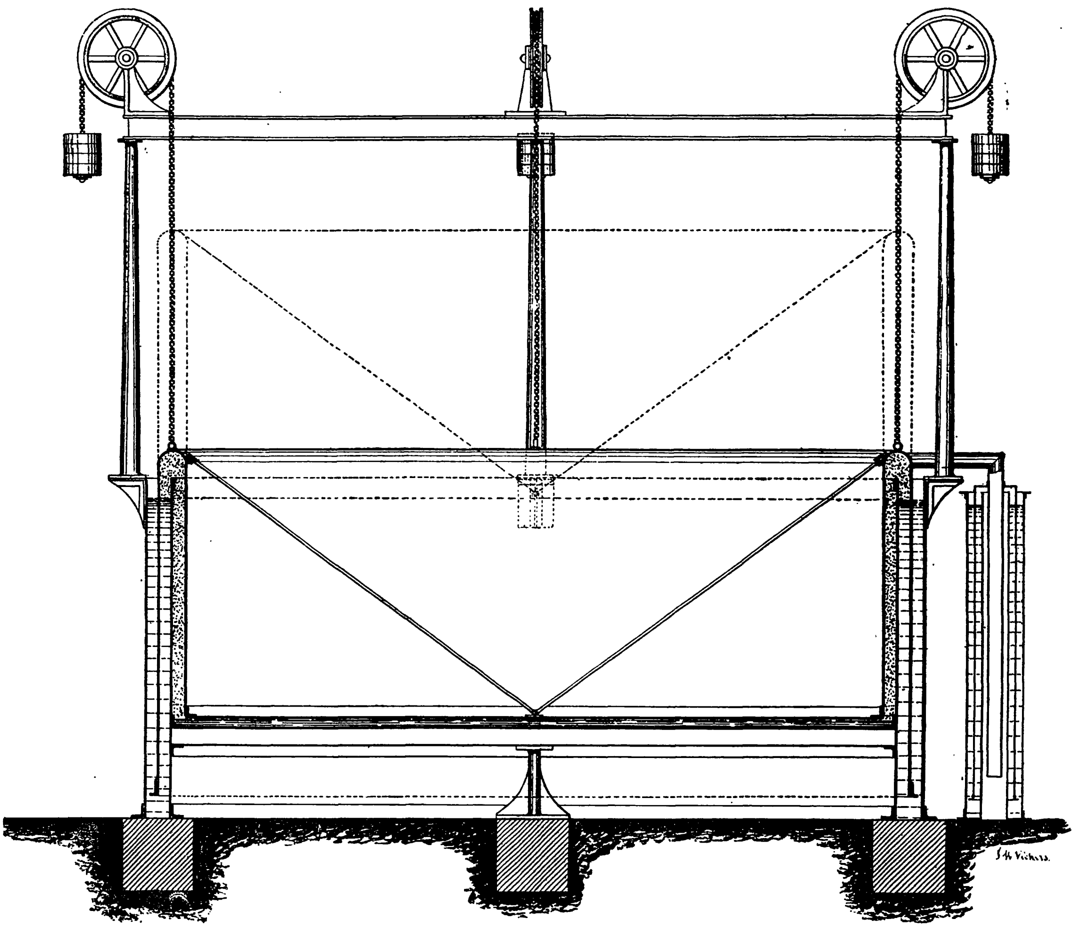
It is highly desirable to be able to store with safety the different petroleum oils. The essential point is to have the oils stored in something like ordinary coal-gas tanks without exposure to the air, because, if exposed to the atmosphere, a small portion of every oil evaporates rapidly, and forms inflammable mixtures with the air above. The model, Fig. 38 (p. 1037), gives you a sectional view of Thwaite's safety oil storage tank. The cover-plate is kept on constantly in contact with the oil and counterbalanced by weights to give the oil only a slight pressure of one or two inches of water. The frame moves into this annular water-seal stand-pipe to the right (Fig. 38), by which any gas that collects may be drawn off by the pipe and utilised. There is no necessity for the introduction of air to empty the tank; the oil is kept cool under very slight pressure, and there is no space left to allow a dangerous explosive mixture to accumulate inside the tank.

Underground tanks built in cement, and

lined with lead or tin, are sometimes employed for storage. This should be surrounded by an embankment, fitted to contain all the oil in case of accident, without allowing any to flow away.

The British Government would do well to establish a proper system of safe oil storage tanks at all the coaling stations. Such storage-tanks would remove one of the difficulties in the way of liquid fuel, and thereby encourage and facilitate the advancement of this important industry, and at the same time secure greater safety to the general public in the use of these oils.

FIG. 38.



OIL STORAGE TANK.—SECTIONAL VIEW.

PETROLEUM AS A LUBRICANT.

The extensive use of mineral oil as a lubricant, including even crude petroleum as well as the suitable distilled products, may perhaps be referred to in considering the uses of petroleum in prime movers. Apart altogether from the use of petroleum as fuel in the cylinder of the Priestman oil-engine, I pointed out to you that the condensed oil-vapour lubricates the cylinder, and contributes to the smooth running of that engine.

Mr. Urquhart gets the pure petroleum refuse by skimming the cream off the oil after settling in the reservoirs, and finds this refuse makes an excellent lubricant for the railway wagons and tenders.

The crude oil is also used for lubrication in the oil-regions of America.

A large variety of mineral lubricating oils are manufactured from the residues left after the lighting-oils at the refineries, by (1) distillation with superheated steam and (2) subsequent chemical purification, including filtration

through animal charcoal to improve their colour and odour.

A serious objection to animal and vegetable oils as lubricants is their tendency to take up oxygen from the air, to become oxidised, causing "gumming" and heating. In this way cotton or woollen waste smeared with these oils, when left exposed to the air, gets heated, and may cause spontaneous ignition, or perhaps a serious fire in a cotton mill. Mineral oils are free from this tendency to oxidise, and when mixed with animal and vegetable oils render these less liable to excite spontaneous combustion.

The function of a lubricant is to keep two sliding or moving surfaces apart, by forming between them a thin film, which reduces the frictional resistance, so that the solid surfaces work together smoothly, thereby preventing undue heating and wear of the working parts, and at the same time effecting a saving in the driving power.

The oil must be thick enough not to be squeezed out from between the surfaces by the greatest working pressure, or at the highest allowable temperature. Different mineral oils are, therefore, selected to suit various purposes. Thus thin oils are suitable for light and delicate working parts, whilst heavy viscous oils, with greater body, as semi-solid lubricants, will do best for heavy machinery.

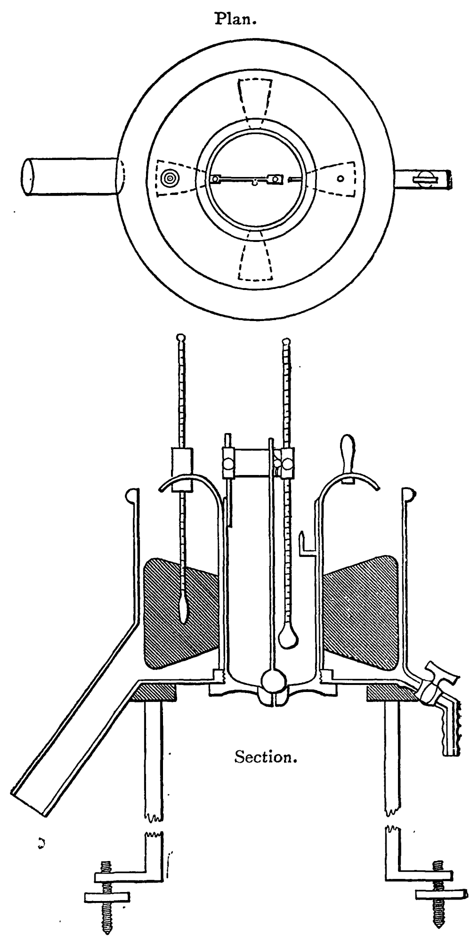
Experience abundantly proves that the frictional resistance does not depend alone upon the true fitting and nature of the solid surfaces, but largely upon the nature of the lubricant that keeps them apart. In fact, the motion is not so much between the solid surfaces as between the particles of the oil or other lubricant. This resistance which a liquid or any fluid offers to sudden change of form, is really a *yielding rigidity* called *viscosity;* and this property of an oil comes most into play for lubricating purposes.

We must, therefore, in every case select an oil of suitable viscosity, at the desired temperature, for the pressure and relative motion between the moving parts. Although the thickest and most viscous oils may suit heavy work and high temperature, it does not follow that they are the best lubricants in every case. After all, experience is the best test of a lubricating oil for any given journal or bearing.

Boverton Redwood's Viscometer.

It appears that there is a relation between the viscosity and lubricating power of an oil, so that, if we find in practice the proper oil for some particular purpose, we may at any future time test the viscosity of a sample, in order to find whether it is the same as the oil previously used. We have here on the table, and Fig. 39 shows a plan and sectional elevation of the standard viscosity meter, or viscometer, devised by Mr. Boverton Redwood, *to measure the viscosity of lubricating oils by the length of time occupied by a given quantity of the oil in flowing through a small orifice at a given temperature.*

Fig. 39.



Boverton Redwood's Viscometer.

The Redwood viscometer (Fig. 39) and its use are thus described:—The instrument consists of a silvered brass oil-cylinder, furnished with an agate jet, and surrounded by a copper bath. A copper tube, closed at the lower end, projecting at an angle of 45° from the side of the bath, near the bottom, provides a means of heating the bath

liquid, and by the use of a revolving agitator, which forms part of the apparatus, the heated liquid rising from the copper tube can be uniformly distributed throughout the bath. The agitator carries a thermometer to indicate the temperature of the bath. The oil-cylinder is furnished with a stopper, consisting of a small brass sphere attached to a wire, the sphere resting in a hemispherical cavity in the agate jet. A short standard, attached to the oil-cylinder, carries a clip to support a thermometer in the oil. Inside the oil-cylinder, and at a short distance from the top, is fixed a small bracket, terminating in an up-turned point, which forms a gauge of the height of the oil-level. The instrument is supported on a tripod stand provided with levelling screws.

Directions for Use.—The jet should be carefully examined before the apparatus is used, and, if necessary, should be cleaned by passing a piece of soft string through it. The apparatus should be adjusted by means of the levelling screws, so that a spirit level placed on the top of the oil-cup shows it to be horizontal.

The bath is filled with a suitable liquid, to a height roughly corresponding with the point of the gauge in the oil-cylinder. Water answers well for temperatures up to 200° F., and for higher temperatures a heavy mineral oil may be used. The liquid, having been brought to the required temperature, the oil to be tested, previously brought to the same temperature, is poured into the oil-cylinder, until the level of the liquid just reaches the point of the gauge. A narrow-necked flask, holding 50 cubic centimetres to a point marked on the neck, is placed beneath the jet in a vessel containing a liquid of the same temperature as the oil. The ball valve is then raised, a stop-watch at the same time started, and the number of seconds occupied in the outflow of 50 c.c. noted. It is of the greatest importance that the oil-cylinder should be filled exactly to the point of the gauge, after inserting the thermometer, and that the given temperature should be precisely maintained during the experiment, a difference of ½° F. making an appreciable alteration in the viscosity of some oils. It is also essential that the oil should be quite free from dirt or other suspended matter, and from globules of water, as the jet may be otherwise partially obstructed. If the oil-cylinder requires to be wiped out, paper rather than cloth should be employed, as filaments of the latter may be left adhering. When oils are being tested at temperatures much above that of the laboratory, a gas flame is applied to the copper heating tube, and the agitator kept in gentle motion throughout the experiment.

Mr. Redwood recommends that the number of seconds occupied in the outflow of 50 cubic centimetres of the oil under examination should be multiplied by 100, and divided by 535 (the number of seconds occupied in the outflow of 50 c.c. of average refined rape oil at 60° Fahr.). The resulting figures should then be multiplied by the specific gravity of the oil under examination at the temperature of the experiment, and divided by 915 (the sp. gr. of refined rape oil at 60° Fahr.); the necessary correction for specific gravity being thus made, the final figures will express the viscosity of the oil, at the temperature of the test, in terms of the viscosity of refined rape oil at 60° Fahr.

$$\text{Viscosity} = \frac{\text{Seconds of flow} \times 100 \times \text{sp. gr. of sample.}}{535 \times 915}$$

Each instrument is carefully standardised, and admits of being employed for the accurate determination of viscosities at temperatures up to 300° Fahr., or even higher.

The oils are usually tested at two points, say 70° Fahr. and 140° Fahr., within which range the oil is likely to be used. The viscosity within these limits of temperature gives you some idea of the "body," or yielding rigidity of the oil, which enables it to keep the metal surfaces apart, and to allow them to move freely. The more viscous an oil, the greater the pressure necessary to squeeze it out from between the moving surfaces. Increase of temperature seriously diminishes the viscosity of an oil, and, therefore, every oil should be tested, if possible, at the temperature it is likely to be used. The variation in the viscosity of different oils, as determined by means of this instrument, is seen by Table VII. (p. 1040), which gives the number of seconds* taken by 50 cubic centimetres of the oil in flowing through the orifice at 60° Fahr.

The viscosity of the mineral lubricating oil should be suited to the usual *temperature* of the journal, at a given *speed* and *pressure* as in practice. Having once found an oil suited to the exact conditions, it is easy to compare new samples.

Besides the determination of the (1) specific gravity, and (2) viscosity, the other physical tests of lubricating oils are (3) effects of heat on nature of lubricants as regards—

* See paper in "Journal of Society of Chemical Industry," vol. v., 1886, p. 128.

(a) Flashing Point (Abel test), which must never be below 250° Fahr., so that no inflammable vapour is given off at any time in practice.

(b) Fire-Test, by Pensky apparatus. In the fire-test the oil-cup is open, exposed to the air, and the bath heated in a cast-iron vessel. The oil should be heated at the rate of 10° Fahr. per minnte.

(c) Volatility, or loss of weight by evaporation when heated in an air bath, so that there may be no loss in every day working. A good oil must not evaporate more than 5 per cent. in ten hours at 60° Fahr., else the bearing is too much dried, and a gum formed. A mineral oil burns without leaving any residue or deposit.

(d) Cold Test.—The temperature at which the oil becomes cloudy and thickens, ceases to flow in a test tube about $1\frac{5}{8}$ inch in diameter, when cooled by a freezing mixture, and the temperature noted at which crystals of solid paraffin are formed. The oil should remain fluid, or like jelly, but never solid, at the lowest winter temperature. The lower the cold test, the better the oil.

(e) Gumming, or tendency to oxidise on exposure to the air, or when in use, is highly objectionable. A small quantity of the sample is allowed to flow down an inclined plane, and the rate of flow observed. Because of this property animal and vegetable oils are inferior to mineral oils. The gumming is due to oxidation, and the presence of free acid, which also acts on and corrodes the metallic surfaces it is used to lubricate. Hence pure mineral oils are best suited for lubrication of high-pressure steam-engine cylinders and valves, &c. Mixtures of mineral with fixed oils, animal or vegetable, although said to be well adapted

to some kinds of moving surfaces, are to be looked upon with suspicion.

In short, heavy mineral oils are specially valuable for lubrication, because they retain their good properties when heated, and do not thicken and oxidise like fixed oils.

Various machines, such as that of Professor Thurston, have been devised to test the relative value of lubricating oils, by using samples of them in journals, under varying conditions of pressure, speed, and temperature. The results thus obtained are not always satisfactory, since they are sometimes found not to agree with practice under every-day working conditions.

Mineral lubricating oils are now being used on all kinds of spindles and machinery. The manufacture of these lubricants from petroleum has been rapidly increasing for some years, and already we can have mineral oils suitable for every prime mover, reducing the frictional resistance of the moving parts, and thus proving to be a cheap and safe lubricant.

Conclusion.

At the outset I enumerated the different kinds of petroleum available for use in prime movers. Throughout this course of lectures I have endeavoured to show you a special use for every kind of petroleum oil; and that all the oils can be employed advantageously in one way or another in prime-movers.

Hitherto the burning oils have been almost exclusively used for lighting purposes; now the same kerosene oil is burned in the cylinder of the modern petroleum engine, and develops power to drive dynamo-electric machines, which generate electricity for lighting and power purposes, doing so both efficiently and economically. The young oil-engine is growing rapidly in power and numbers, and, being self-contained, is proving a more convenient and economical prime mover than either gas or steam-engines, for small powers at least. The common petroleum oil, used in this engine both as fuel and working agent, is to be had in abundance in many parts of the British dominions, and there is good reason to expect, from the wholesale prices already quoted, that the petroleum industry is rapidly extending into fresh fields, and the production of oil is daily increasing.

Engineers, true to their duty, are directing these great stores or sources of power in Nature to the use and convenience of man. We may then look with confidence to the rapid development of the common oil engine.

Practical utility points to the waste refuse from the oil-field or gas works, and turns even this form of petroleum to good account as liquid fuel.

I have not been able to do justice to this important subject in the limited time at our disposal. However, I trust you now look upon common petroleum as a more useful and less dangerous liquid than is commonly supposed. If I have in any way added to your interest in this subject, or suggested thoughts to anyone who may be working at it, and by that means advanced it somewhat, I shall be fully rewarded for trespassing to such length on your patience.

In conclusion, my thanks are due to the gentlemen who supplied me with engines, apparatus, and diagrams for illustrations, and for assistance in various ways. I wish to thank my students for preparing drawings, and especially Mr. Edward Arnold Medley for his kind and zealous help.

Miscellaneous.

COLLECTION OF MINERALS FOR THE CHICAGO EXHIBITION.

It will be remembered that the Royal Commission for the Chicago Exhibition, anxious to comply with a request made to them by the executive authorities, arranged to include in the British Section a typical collection of economic British minerals, and asked for the co-operation of owners and managers of mines in carrying this proposition into effect. At the close of the Exhibition the collection would, it was decided, be presented to an American museum so that it might have a permanent value, and in order to secure uniformity it was required that the specimens should be of such size that they would lie on trays measuring six inches by four inches. Mr. Bennett Brough, of the School of Mines, Royal College of Science, South Kensington, who has kindly undertaken to receive, classify, and arrange the collection, has received a fair number of specimens. The following are particulars of the more important contributions to the collection.

Mr. A. Forster sends an interesting series of specimens of barytes from Bantry, Ireland, and Mr. G. L. Tottenham a similar series from County Leitrim. Specimens of barytes have also been received from Snailbeach Mine, Shropshire, and from Mawsden Mine, Derbyshire. Messrs. Pike Brothers, of Wareham, Dorset, send a sample of their clay used for the manufacture of fine white earthenware. It is technically known as "blue ball clay," and it is interesting historically to note that this clay was used

by Josiah Wedgwood in 1791. The North Devon Clay Company of Torrington, Devon, send a series of specimens of clay, and a photograph showing the open workings. The clay is cut by one man in a straight line, and then is cut across by a second; a third undercuts with an adze, clearing out the clay in 8-inch cubes. The Coniston Mining Syndicate send a handsome specimen of copper pyrites. Specimens of gypsum have been received from the Sub-Wealden Gypsum Company and from the Vale of Belvoir and Newark Plaster Company. Iron ore is well represented. The Hodbarrow Mining Company, Millom, Cumberland, send some fine specimens of their Hodbarrow red hæmatite ore, carefully selected by Mr. Cedric Vaughan. Red hæmatite has also been received from the Park Iron Mines Company, whilst the Lincolnshire iron ore deposits are represented by a series of specimens from the Midland Company's ironstone mines at Frodingham. These are accompanied by a statement of the results of analyses specially made. Lead ore, from the Mawsden Mine in Derbyshire, has been received from Mr. W. Bowman. Specimens of this ore have also been received from the Snailbeach Mine; the Milwr Mining Company, near Holywell, Flintshire; the Coniston Mining Syndicate, Lancashire; the Rushen Mine, Isle of Man; the East Durren Mine; and the Old Gang Lead Mines, Swaledale. Lastly, the Halkyn Mining Company send a complete series of specimens from their mine near Holywell, probably the richest lead mine in Great Britain. Manganese ore, from Beneult Mine, Rhiw, is contributed by Mr. J. Roberts. Ochre, crude yellow ochre, and pond ochre, has been received from the Cronebane and Tigroney Mining Company, from their mines at Avoca, in County Wicklow. Cornwall is represented by a fine series of tin ores from South Condurrow Mine, carefully selected by Mr. W. Rich. Witherite, a mineral worth about £5 per ton, is included in the contributions from the Snailbeach and Old Gang Mines, and specimens of zinc-blende and calamine have been received from the Mawsden Mine, Derbyshire; from Trecastell Mine, Conway, North Wales; from the Milwr Mining Company; and from the Halkyn Mining Company.

The collection of typical coals is as yet incomplete. Prof. Merivale has kindly promised to select hand specimens of north country coals, and Mr. H. W. Hughes specimens of South Staffordshire coals, whilst the Forest of Dean is already well represented by specimens sent by the Park Iron Mines and Colliery Company. Thanks to the energy of Mr. J. R. W. Eldridge, specimens illustrative of the mining industry of the Wakefield district have been collected by the Wakefield Chamber of Commerce. This collection includes samples of coal from Messrs. J. and J. Charlesworth, Messrs. Terry, Greaves and Co., the Victoria Coal and Coke Co., Limited, and Messrs. J. J. W. Woodhead; whilst alumstone, stone, and lead ore are contributed by Messrs. J. H. Cookson and Son, Mr. J. J. Hulbert, and the North Wales Lead Works, Limited.

Specimens of uranium ore have been promised by Mr. Thomas, and numerous other promises have been received, so that, although there are numerous gaps still to be filled, it appears probable that, thanks to the liberality of mine-owners and managers, a thoroughly typical collection will be got together.

The Royal Commission will be glad to receive from mine-owners, and others interested in mineralogy, contributions of any British minerals of economic importance not referred to in the above list.

EDUCATION AND THE PRESS IN BRITISH INDIA.

In a publication issued by the India-office it is stated that education continues to make progress in India, though the proportion of the total population able to read and write, and the proportion of children of school-going age under instruction are still very small in every province except Burma. The number of schools and colleges in British India increased from 134,710 at the beginning to 138,054 at the end of the year 1890-91, and the total number of scholars rose during the same period from 3,626,390 to 3,682,707. Of this latter number, 313,777, as against 294,457 in the previous year, were girls. It is estimated that in British India 19·3 per cent. of all the boys of school-going age attended school, but for girls of school-going age the per-centage was only 1·8 per cent. The total number of scholars are 11·4 per cent. of all children of school-going age of both sexes. At the five universities which hold examinations, grant degrees, and practically control higher and secondary education throughout India, there were 15,589 undergraduates studying at 136 colleges, among whom 76 were girls. The number of students who gained university degrees were—in arts and sciences, 1,348; in law, 224; in medicine, 78; and in engineering, 108. A large number of students obtained subordinate diplomas in medicine, engineering, and agriculture, who had not passed through the full university course. The number of students who presented themselves for the entrance or matriculation examination at the several examinations was 17,254 boys and 142 girls, out of whom 5,377 boys and 79 girls passed. The number of scholars learning English was 353,515. There were 121 training schools for schoolmasters, and 35 for schoolmistresses; from these institutions 1,892 men and 211 women gained certificates as qualified teachers. The number of technical institutions in British India was returned at 17 medical schools, 25 engineering and surveying schools, 4 schools of art, 71 industrial schools, 3 veterinary, and 2 agricultural schools. The most important technical schools are those maintained at the workshops of the great railways. The year showed an increase in the number of scholars of all creeds except Mohammedan; the total number of

Moslem scholars decreased from 854,498 in the previous year to 836,389; among other classes of scholars there were 2,512,916 Hindoos, 25,568 Europeans and Eurasians, and 86,314 native Christians. The total expenditure on education during the year was Rx.2,888,000 as compared with Rx.2,766,000 in the preceding year. During the year 1890-91 there were 573 newspapers and periodicals published in 16 different languages of India. The largest circulation of any daily journal was returned at 1,500, and of any weekly at 20,000 copies. The former was the Guzerathi *Samachar*, and the latter was the Bengali *Bangabusi*. There was no censorship on any of these journals and no restriction beyond the general law against libel, against indecency, and against exciting sedition; but abstracts of articles and intelligence in vernacular newspapers are laid every week before the local and supreme Governments. The total number of books and publications registered during the year was 7,658, or 22 per cent. below the number of the preceding year; about 92 per cent. of these were in vernacular languages, and many were republications or new editions of old works. The subject of the greater number of these works fell under the heads of language and school books, religion, poetry, drama, and fiction.

General Notes.

CIGARETTES IN MEXICO.—The *Mexican Financial Review* says that the manufacture of cigarettes by hand in the city of Mexico has increased enormously in the last five years, notwithstanding the fact that several machines have been invented for making them. There are 3,000 persons, mostly women, employed in the manufacture of cigarettes, and the average produced by each person is 2,000 per day, or a daily total of 6,000,000, equal to 1,728,000,000 cigarettes a year. The average price paid to the operatives is 20 cents per thousand, which is equivalent to 1,200 dollars daily wages, or 345,000 dollars per annum distributed among the 3,000 operatives. The number of working days in a year, exclusive of Sundays and holidays, is 288. These figures refer only to the cigarettes made by hand in the city of Mexico, he statistics as to those made by machinery not being available, and in addition very large quantities of cigarettes are imported from Havana.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, Nov. 14...Royal Scottish Society of Arts, 117, George-street, Edinburgh, 8 p.m. Opening Address by the President, Mr. Alexander Leslie.

Surveyors, 12, George-street, S.W., 8 p.m. Opening Address by the President, Mr. Charles J. Shoppee.

Geographical, University of London, Burlington-gardens, W., 8½ p.m. Dr. Fridtjof Nansen, "On his proposed Expedition across the North Polar Region."

London Institution, Finsbury-circus, E.C., 5 p.m. Prof. Sir Robert Ball, "Auriga" (illustrated).

TUESDAY, Nov. 15...Society of Architects, St. James'-hall, Piccadilly, W., 3 p.m. Opening Address by the President, Mr. Robert Walker.

Civil Engineers, 25, Great George-street, S.W., 8 p.m. 1. Hon. R. C. Parsons, "Halifax Graving-Dock, Nova Scotia." 2. Mr. E. W. Young, "Cockatoo Island Graving-Dock, New South Wales." 3. Mr. W. Redfern Kelly, "The Alexandra Graving-Dock, Belfast." 4. Mr. Robert Pickwell, "Construction of a Concrete Graving Dock at Newport, Monmouthshire."

Statistical, Museum of Practical Geology, 28, Jermyn-street, S.W., 7¾ p.m. Inaugural Address by the President, Mr. Charles Booth.

Zoological, 3, Hanover-square, W., 8½ p.m. 1. Messrs. W. Bateson and H. H. Brindley, "Some cases of Variation in Secondary Sexual Characters statistically examined." 2. Mr. G. A. Boulenger, "*Testudo grandidieri*, a new Fossil Giant Tortoise from a Cave in South-west Madagascar." 3. Mr. O. Thomas, "Description of a new Monkey of the Genus *Semnopithecus* from Northern Borneo."

WEDNESDAY, Nov. 16...SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Opening Meeting of the Session. Inaugural Address by Sir Richard Webster, Chairman of the Council.

Meteorological, 25, Great George-street, S.W., 7 p.m. 1. Mr. John Lovel, "Thunderstorm, Cloud-burst, and Flood at Langtoft, East Yorkshire, July 3rd, 1892" 2. Mr. W. H. Dines, "The measurement of the maximum Wind Pressure, and Description of a new Instrument for indicating and recording the maximum."

Microscopical, 20, Hanover-square, W., 8 p.m. 1. Mr. F. Chapman, "Foraminifera of the Gault of Folkestone." 2. Mr. C. Haughton Gill, "Fungoid growths on Diatoms." 3. Mr. John Hood, "*Notops ruber*, a new rotifer."

THURSDAY, Nov. 17...Linnean, Burlington-house, W., 8 p.m. 1. Rev. Prof. Henslow, "A Theoretical Origin of Endogens through an Aquatic Habit." 2. Mr. G. Lewis, "The Buprestidæ of Japan and their Coloration."

Chemical, Burlington-house, W., 8 p.m. 1. Prof. Thorpe and Mr. William Kirman, "Fluosulphonic Acid." 2. Prof. Thorpe and Mr. George H. Perry, "The Interaction of Iodine and Potassium Chlorate." 3. Mr. W. H. Perkin, "Magnetic Rotation of Sulphuric and Nitric Acids, and their Solutions; also of Solutions of Sodium Sulphate and Lithum Nitrate." 4. Mr. S. U. Pickering, "Note on the Refractive Indices and Magnetic Rotation of Sulphuric Acid Solutions." 5. Mr. S. U. Pickering, "Hydrates of Alkylamines." 6. Prof. Ramsay and Miss Emily Aston, "The Atomic Weight of Boron," and other papers.

London Institution, Finsbury-circus, E.C., 6 p.m. Rev. Canon Edmund Venables, "Lincoln Cathedral."

Historical, 20, Hanover-square, W., 8½ p.m. Prof. Julius von Pflugk-Harttung, "The Druids of Ireland."

The Telegraphic Address of the Society of Arts, and of the Royal Commission for the Chicago Exhibition, is "Praxiteles, London."

CONTRIBUTIONS TO THE READING-ROOM.

The Council beg leave to acknowledge, with thanks to the Proprietors, the regular receipt of the following Transactions of Societies and Periodicals.
